23. CYCLE EXPANSIONS

is entire and calculations are super-exponentially convergent, cycle expansion of the corresponding dynamical zeta function (22.28) has a finite radius of convergence and captures only the leading eigenvalue, at exponentially convergent rate.

23.1 Pseudo-cycles and shadowing

How are periodic orbit formulas such as (22.11) evaluated? We start by computing the lengths and Floquet multipliers of the shortest cycles. This always requires numerical work, such as searches for periodic solutions via Newton’s method; we shall assume for the purpose of this discussion that the numerics is under control, and that all short cycles up to a given (topological) length have been found. Examples of the data required for application of periodic orbit formulas are the lists of cycles given in exercise 7.2 and table 33.3. Sadly, it is not enough to set a computer to blindly troll for invariant solutions, and blithely feed those into the formulas that will be given here. The reason that this chapter is numbered 23 and not 6, is that understanding the geometry of the non–wandering set is a prerequisite to good estimation of dynamical averages: one has to identify cycles that belong to a given ergodic component (whose symbolic dynamics and shadowing is organized by its transition graph), and discard the isolated cycles and equilibria that do not take part in the asymptotic dynamics. It is important not to miss any short cycles, as the calculation is as accurate as the shortest cycle dropped – including cycles longer than the shortest omitted does not improve the accuracy (more precisely, the calculation improves, but so little as not to be worth while).

Given a set of periodic orbits, we can compute their weights \( t_p \) and expand the dynamical zeta function (22.11) as a formal power series,

\[
1/\zeta = \prod_p (1 - t_p) = 1 - \sum_{\{p_1 \cdots p_k\}} (-1)^{k+1} t_{p_1} t_{p_2} \cdots t_{p_k}
\]

where the prime on the sum indicates that the sum is over all distinct non-repeating combinations of prime cycles. As we shall frequently use such sums, let us denote by \( t_p = (-1)^{k+1} t_{p_1} t_{p_2} \cdots t_{p_k} \) an element of the set of all distinct products of the prime cycle weights \( t_{p_k} \), and label each such pseudo-cycle by

\[
\pi = p_1 + p_2 + \cdots + p_k
\]

The formal power series (23.1) is now compactly written as

\[
1/\zeta = 1 - \sum\limits_\pi t_\pi
\]

For \( k > 1 \), the signed products \( t_\pi \) are weights of pseudo-cycles; they are sequences of shorter cycles that shadow a cycle with the symbol sequence \( p_1 p_2 \cdots p_k \) along the segments \( p_1, p_2, \ldots, p_k \), as in figure 1.12. The symbol \( \sum\limits_\pi \) denotes the restricted sum, for which any given prime cycle \( p \) contributes at most once to a given pseudo-cycle weight \( t_\pi \).
The pseudo-cycle weight, i.e., the product of weights (22.9) of prime cycles comprising the pseudo-cycle,

\[ t_\gamma = (-1)^{k+1} \frac{1}{|A_\gamma|} \mu(A_\gamma) \varepsilon^n, \]

depends on the pseudo-cycle integrated observable \( A_\gamma \), the period \( t_\gamma \), the stability \( \Lambda_\gamma \).

\[ A_\gamma = A_{p_1} A_{p_2} \cdots A_{p_k}, \quad T_\gamma = T_{p_1} + \cdots + T_{p_k} \]

\[ A_\gamma = A_p + \cdots + A_p, \quad n_\gamma = n_{p_1} + \cdots + n_{p_k}, \]

and, when available, the topological length \( n_\gamma \).

### 23.1.1 Curvature expansions

The simplest example is the pseudo-cycle sum for a system described by a complete binary symbolic dynamics. In this case the Euler product (22.11) is given by

\[ t_\gamma = (1-t_0)(1-t_1)(1-t_{01})(1-t_{001})(1-t_{0001})(1-t_{00001}) \times (1-t_{000001})(1-t_{0000001})(1-t_{00000001})(1-t_{000000001}) \cdots \]

(see table 18.1), and the first few terms of the expansion (23.3) ordered by increasing total pseudo-cycle length are:

\[ t_\gamma = 1 - t_0 - t_1 - t_{01} - t_{001} - t_{0001} - t_{00001} - t_{000001} - t_{0000001} - \cdots \]

\[ + t_{0011} + t_{0101} + t_{0110} + t_{1001} + t_{1010} + t_{1100} + t_{1101} + t_{1110} + t_{1111} \]

\[ = 1 - \sum_j t_j - \sum \xi_\gamma > \]

We refer to such series representation of a dynamical zeta function or a spectral determinant, expanded as a sum over pseudo-cycles, and ordered by increasing cycle length and instability, as a cycle expansion.

The next step is the key step: regroup the terms into the dominant fundamental contributions \( t_j \) and the decreasing curvature corrections \( \xi_\gamma \), each \( \xi_\gamma \) split into prime cycles \( p \) of length \( n_p = n \) grouped together with pseudo-cycles whose full itineraries build up the itinerary of \( p \). For the binary case this regrouping is given by

\[ \frac{1}{\zeta} = 1 - t_0 - t_1 - \{ (t_01 - t_{01}) + (t_{011} - t_{011}) + (t_{0011} - t_{0011}) + (t_{00011} - t_{00011}) \}
\]

\[ - \{ (t_{0011} - t_{0011}) + (t_{0111} - t_{0111}) + (t_{000111} - t_{000111}) + (t_{0000111} - t_{0000111}) \} \cdots \]

\[ = 1 - \sum_j t_j - \sum \xi_\gamma \]

### 23.2 Construction of cycle expansions

Due to the lack of factorization of the determinant in the denominator of the full pseudo-cycle weight in (21.19),

\[ \det \left( 1 - M_{p,p} \right) \neq \det \left( 1 - M_p \right) \det \left( 1 - M_p \right), \]

the cycle expansions for the spectral determinant (22.8) are somewhat less transparent than is the case for the dynamical zeta functions, so we postpone their evaluation to sect. 23.2.2. Sect. 23.2.1 is a pedagogical warmup. In actual calculations, implementing the spectral determinant cycle expansions of sect. 23.2.2 is
Table 23.1: The binary curvature expansion (23.8) up to length 6, listed in such a way that the sum of terms along the path horizontal line is the curvature $\xi_p$ associated with a prime cycle $p$, or a combination of prime cycles such as the $t_{0001} + t_{0010}$ pair.

</table>

23.2.2 Evaluation of traces and spectral determinants

We commence the cycle expansion evaluation of a spectral determinant by computing the trace formula (21.19) or (21.19). The weight of prime cycle $p$ repeated $r$ times is

$$ t_p(z, \beta, r) = \frac{\epsilon^{\beta n_p}}{\det\{1 - M_p\}} (\text{discrete time}) $$

$$ t_p(s, \beta, r) = \epsilon^{\beta (s \beta - s p)} (\det\{1 - M_p\}) (\text{continuous time}) $$

For discrete time, the trace formula (21.19) truncated to all prime cycles $p$ and their repeats $r$ such that $n_p \leq N$,

$$ \text{tr} \frac{z L}{1 - z L(p)} = \sum_{n=1}^{N} C_n z^n, \quad C_n = \text{tr} L^n, \quad (23.13) $$

is computed as a polynomial in $z$ by adding a cycle at the time:

$$ \text{tr} \frac{z L}{1 - z L(p)} = \text{tr} \frac{z L}{1 - z L(p - 1)} + \sum_{n=1}^{n \leq N} t_{n}(z, \beta, r). $$

For continuous time, we assume that the method of Poincaré sections assigns each cycle a topological length $n_p$. Then the trace formula (21.19) is also organized as a polynomial

$$ \text{tr} \frac{1}{s - A_N} = \sum_{n=1}^{N} C_n s^n, \quad (23.14) $$

computed as:

$$ \text{tr} \frac{1}{s - A_N} = \text{tr} \frac{1}{s - A_{p - 1}} + T_{i \leq N} t_{i}(z, \beta, r) z^{n_i} $$

The periodic orbit data set (23.5) consists of the list of the cycle periods $T_p$, the cycle Floquet multipliers $\Lambda_{s, \beta, z}$, and the cycle averages of the observables $A_p$ for all prime cycles $p$ such that $n_p \leq N$. The coefficient of $z^{n_i}$ is then evaluated numerically for the given parameter values $(\beta, s)$. Always compute the leading eigenvalue of the evolution operator first, i.e., the escape rate $\gamma = -\xi_0$, in
order to use it in calculation of averages of sect. 23.5 as a weight
as follows. The logarithmic derivative relation (22.4) yields
\[
\frac{d}{dz} \log \frac{1}{1 - Q_n} = n \frac{dz}{1 - zL}
\]
so the nth order term of the spectral determinant cycle (or in this case, the cumulant) expansion is given recursively by the convolution trace formula expansion coefficients
\[
Q_n = \frac{1}{n} \left( C_n + C_{n-1} Q_1 \cdots C_1 (Q_{n-1}) \right), \quad Q_1 = C_1.
\]
Given the trace formula (23.13) truncated to \( z^n \), we now also have the spectral determinant truncated to \( z^n \).

The same program can also be reused to compute the dynamical zeta function cycle expansion (23.10), by replacing \( \prod (1 - \Lambda(i)) \) in (23.13) by the product of expanding eigenvalues \( \Lambda(i) = \prod |\Lambda(i)_{\alpha} \cdot e^{2\pi i \phi} | \).

A few points concerning different cycle averaging formulas:

- The dynamical zeta functions is an approximation to spectral determinant that yields only the leading eigenvalue of the evolution operator. The cycle weights depend only on the product of expanding \( |\Lambda(i)_{\alpha} \cdot e^{2\pi i \phi} | \) Floquet multipliers, so signs do no matter. For hyperbolic flows they converge exponentially with increasing cycle lengths.

- Spectral determinants weights in (23.3) contain \( 1/|1 - \Lambda(i)| \) factors, so for them signs of Floquet multipliers \( \Lambda(i) \) do matter. With finite grammar the leading eigenvalue converges super-exponentially in cycle length.

Note that while the dynamical zeta functions weights use only the expanding Floquet multipliers \( \Lambda(i) \) for spectral determinants the weights are of form \( 1 - \Lambda(i) \), both expanding and contracting directions contribute, and the signs of multipliers do matter. That’s why ChaosBook everywhere tracks expanding eigenvalues \( \Lambda(i) \), rather than Floquet exponents \( \lambda(i) \), it’s belong to equilibria, periodic orbits require multipliers. That’s the way cookie crumbles. For very high-dimensional flows (such as unstable periodic solutions of Navier-Stokes equations), usually only a subset of the most unstable / least contracting Floquet multipliers is known. As long as the contracting Floquet multipliers omitted from the weights in (23.13) are sufficiently strongly contracting, the errors introduced by replacement \( |1 - \Lambda(i)| \rightarrow 1 \) for such eigenvalues should be negligible.

### Table 23.2: The 3-disk repeller escape rates computed from cycle expansions of the spectral determinant (22.5) and the dynamical zeta function (22.11), as functions of the maximal cycle length \( N \). The disk-disk center separation to disk radius ratio is \( R/a \), and the disk-disk center separation to disk radius ratio is \( \alpha \). The 3-disk repeller escape rates computed from cycle expansions of the spectral determinant (22.5) as a power series, we compute the \( N \)th order approximation to the spectral determinant (22.3),

\[
\det(1 - zL)_{\alpha} = 1 - \sum_{n=1}^{N} Q_n z^n, \quad Q_n = \text{nth cumulant},
\]
as follows. The logarithmic derivative relation (22.4) yields

\[
\frac{d}{dz} \log \frac{1}{1 - zL} = -z \frac{d}{dz} \det(1 - zL)
\]

\[
(C_1 z + C_2 z^2 + \cdots)(1 - Q_1 z - Q_2 z^2 - \cdots) = Q_1 z + 2Q_2 z^2 + 3Q_3 z^3 \cdots
\]

so the nth order term of the spectral determinant cycle (or in this case, the cumulant) expansion is given recursively by the convolution trace formula expansion coefficients

\[
Q_n = \frac{1}{n} \left( C_n - C_{n-1} Q_1 \cdots C_1 (Q_{n-1}) \right), \quad Q_1 = C_1.
\]

Given the trace formula (23.13) truncated to \( z^n \), we now also have the spectral determinant truncated to \( z^n \).

The same program can also be reused to compute the dynamical zeta function cycle expansion (23.10), by replacing \( \prod (1 - \Lambda(i)) \) in (23.13) by the product of expanding eigenvalues \( \Lambda(i) = \prod |\Lambda(i)_{\alpha} \cdot e^{2\pi i \phi} | \).

A few points concerning different cycle averaging formulas:

- The dynamical zeta functions is an approximation to spectral determinant that yields only the leading eigenvalue of the evolution operator. The cycle weights depend only on the product of expanding \( |\Lambda(i)_{\alpha} \cdot e^{2\pi i \phi} | \) Floquet multipliers, so signs do no matter. For hyperbolic flows they converge exponentially with increasing cycle lengths.

- Spectral determinants weights in (23.3) contain \( 1/|1 - \Lambda(i)| \) factors, so for them signs of Floquet multipliers \( \Lambda(i) \) do matter. With finite grammar the leading eigenvalue converges super-exponentially in cycle length.

Note that while the dynamical zeta functions weights use only the expanding Floquet multipliers \( \Lambda(i) \) for spectral determinants the weights are of form \( 1 - \Lambda(i) \), both expanding and contracting directions contribute, and the signs of multipliers do matter. That’s why ChaosBook everywhere tracks expanding eigenvalues \( \Lambda(i) \), rather than Floquet exponents \( \lambda(i) \), it’s belong to equilibria, periodic orbits require multipliers. That’s the way cookie crumbles. For very high-dimensional flows (such as unstable periodic solutions of Navier-Stokes equations), usually only a subset of the most unstable / least contracting Floquet multipliers is known. As long as the contracting Floquet multipliers omitted from the weights in (23.13) are sufficiently strongly contracting, the errors introduced by replacement \( |1 - \Lambda(i)| \rightarrow 1 \) for such eigenvalues should be negligible.
23. Cycle Expansions

(i) The system is bounded, and we have all cycles up to some cutoff: always start by testing the cycle expansion sum rules of sect. 23.4.

(ii) The system is unbounded, and averages have to be computed over a repeller whose natural measure is obtained by balancing local instability with the global escape rate \( \gamma = -s_0 \), as in sect. 20.4.

(iii) The system is bounded, but we only have a repelling set consisting of a subset of unstable cycles embedded into the bounded strange attractor. Best one can do is to treat this as an open system, case (iii). That assigns a stationary natural measure to neighborhoods of the solutions used, the local instabilities balanced by a weight that includes escape rate \( \exp(\gamma T_p) \). Whether use of this measure improves averages as one increases the stability cutoff depends on whether the longer cycles explore qualitatively different regions of state space not visited by the shorter (fundamental) cycles, or only revisit already known regions (curvature corrections).

23.4 Flow conservation sum rules

If a dynamical system is bounded, so that all trajectories remain confined for all times, the escape rate (27.8) vanishes \( \gamma = -s_0 = 0 \), and the leading eigenvalue of the Perron-Frobenius operator (19.10) (evolution operator with \( \beta = 0 \)) is simply \( \exp(-\gamma T_p) = 1 \). Conservation of material flow thus implies that for bounded flows cycle expansions of dynamical zeta functions and spectral determinants satisfy exact flow conservation sum rules:

\[
1/\zeta(0,0) = 1 + \sum_{s} (-1)^{s} \frac{1}{|\Lambda_{1} \cdots \Lambda_{s}|} = 0
\]

\[
F(0,0) = 1 - \sum_{n=1}^{\infty} Q_n(0,0) = 0
\]

(23.17)

obtained by setting \( s = 0 \) in (23.18), (23.19) with cycle weights \( t_p = e^{-\gamma T_p} / |\Lambda_p| \rightarrow 1 / |\Lambda_p| \). These sum rules depend neither on the cycle periods \( T_p \), nor on the observable \( n(x) \) under investigation, but only on the cycle stabilities \( \Lambda_{1}, \Lambda_{2}, \ldots, \Lambda_{p,d} \). Their significance is purely geometric; they are a measure of how well periodic orbits tessellate state space, as in figure 1.11. Conservation of material flow provides a first and very useful test of the quality of finite cycle length truncations and is something that you should always check when constructing a cycle expansion for a bounded flow.

- The least enlightened are the ‘level sum’ cycle averaging formulas. There is no point in using them, except that they have to be mentioned (here in sect. 27.4), as there is voluminous literature that uses them.
- Other formulas published in physics literature are likely to be wrong.

If the set of computed periodic orbits is incomplete, and their Floquet multipliers inaccurate, distinctions between different cycle averaging formulas are academic, as there are not sufficiently many cycles to start worrying about what expansion converges faster.

23.3 Periodic orbit averaging

The first cycle expansion calculation should always be the determination of the leading eigenvalue of the evolution operator, calculated as follows. After the prime cycles and the pseudo-cycles have been grouped into subsets of equal topological length, the dummy variable can be set equal to \( z = 1 \). With \( z = 1 \), the expansion (23.15) constitutes the cycle expansion (22.5) for the spectral determinant \( \det(s - A) \). We vary \( s \) in cycle weights, and determine orth eigenvalue \( s_\alpha \) (20.28) by finding \( s = s_\alpha \) for which (23.15) vanishes. As an example, the convergence of a leading eigenvalue for a nice hyperbolic system is illustrated in table 23.2 by the list of pinball escape rates \( \gamma = -s_0 \) estimates computed from truncations of (23.8) and (23.15) to different maximal cycle lengths.

The pleasant surprise, to be explained in chapter 28, is that one can prove that the coefficients in these cycle expansions decay exponentially or even faster, because of the analyticity of \( \det(s - A) \) or \( 1/\zeta(s) \), for \( s \) values well beyond those for which the corresponding trace formula (21.19) diverges.

Our next task will be to compute long-time averages of observables. Three situations arise, two of them equal in practice:
23.5 Cycle formulas for dynamical averages

Want to learn some useful safety maneuvers? Or perhaps you’d like to become a more able mechanic? Or have bike safety questions answered? Or eat pizza? Then sign up for Enlightened Cycling!

— Bike GT: Cycling around Georgia Tech

The eigenvalue conditions for the dynamical zeta function (23.3) and the spectral determinant (23.15),

$$0 = 1 - \sum_n t_n, \quad t_n = t_n(\beta, s(\beta))$$

$$0 = 1 - \sum_n Q_n, \quad Q_n = Q_n(\beta, s(\beta)),$$

are implicit equations for an eigenvalue $s = s(\beta)$ of the form $0 = F(\beta, s(\beta))$. The eigenvalue $s = s(\beta)$ of a function of $\beta$ is sketched in figure 23.2; this condition is satisfied on the curve $F = 0$. The cycle averaging formulas for the slope and curvature of $s(\beta)$ are obtained as in (20.11) by taking derivatives of the eigenvalue condition. Evaluated along $F = 0$, by the chain rule the first derivative yields

$$0 = \frac{d}{d\beta} F(\beta, s(\beta)) = \frac{\partial F}{\partial \beta} + \frac{ds}{d\beta} \frac{\partial F}{\partial s} \bigg|_{s(\beta)} = \frac{ds}{d\beta} = -\frac{\partial F}{\partial \beta} \cdot \frac{1}{\partial s},$$

(23.20)

and the second derivative of $F(\beta, s(\beta)) = 0$ yields

$$\frac{d^2 s}{d\beta^2} = \left[ \frac{\partial^2 F}{\partial \beta^2} + 2 \frac{ds}{d\beta} \frac{\partial^2 F}{\partial \beta \partial s} \right] \frac{1}{\partial s} = \frac{\partial^2 F}{\partial s^2} \cdot \frac{1}{\partial s},$$

(23.21)

the mean cycle expectation value of $A$, the mean cycle period, and second derivatives of $F$ computed for $F(\beta, s(\beta)) = 0$, we obtain the cycle averaging formulas for the expectation of the observable (20.11) and for its (generalized) diffusion constant (or, more generally, diffusion tensor):

$$\langle a \rangle = \frac{\langle A \rangle}{T} = \frac{\langle A \rangle}{\langle T \rangle},$$

(23.23)

and so forth for higher cumulants. These formulas are the central result of periodic orbit theory. We now show that for each choice of the function $F(\beta, s)$ in (23.3) and (23.15) (also the trace, or ‘level sum’ of (27.15)), the above quantities have explicit cycle expansions.

23.5.1 Dynamical zeta function cycle averaging formulas

For the dynamical zeta function condition (23.18), the cycle averaging formulas (23.20), (23.24) require one to evaluate derivatives of dynamical zeta functions at

$$\langle A \rangle = \frac{\langle A \rangle}{T} = \frac{\langle A \rangle}{\langle T \rangle},$$

(23.25)

where the subscript in $\langle \cdots \rangle$ stands for the dynamical zeta function average over prime cycles, $A_\xi = T_\xi$ and $n_\xi$ given by (23.4) are evaluated on pseudo-cycles (23.5), and pseudo-cycle weights $t_\xi = t_\xi(\beta, s(\beta))$ are evaluated at the eigenvalue $s(\beta)$. In most applications $\beta = 0$, and $s(\beta)$ of interest is typically the leading eigenvalue $s_0 = so(0)$ of the evolution generator $\mathcal{A}$.

For bounded flows the leading eigenvalue (the escape rate) vanishes, $s(0) = 0$, the exponent $\beta s_0 = sT_0$ in (23.4) vanishes, so the cycle expansions take a simple form

$$\langle A \rangle = \sum_n (-1)^{n+1} \frac{A_n + A_{n^2} + \cdots + A_{n^m}}{\prod_{i=1}^m A_{\mu_i}},$$

(23.26)
where analogous formulas hold for $\langle T \rangle_\zeta$, $\langle n \rangle_\zeta$.

The cycle averaging formulas for the expectation of observable $\langle a \rangle$ follow by substitution into (23.24). Assuming zero mean drift $\langle a \rangle = 0$, the cycle expansion (23.15) for the variance $\langle (A - \langle A \rangle)^2 \rangle_\zeta$ is given by

$$\langle (A^2) \rangle_\zeta = \sum (-1)^{j+1} \left( \frac{A_{p_1} + \cdots + A_{p_n}}{|A_{p_1} \cdots A_{p_n}|} \right)^2.$$  

(23.27)

### 23.5.2 Spectral determinant cycle expansions

The dynamical zeta function cycle expansions have a particularly simple structure, with the shadowing apparent already by a term-by-term inspection of table 23.2. For “nice” hyperbolic systems, shadowing ensures exponential convergence of the dynamical zeta function cycle expansions. This, however, is not the best achievable convergence. As will be explained in chapter 28, for nice hyperbolic systems the spectral determinant constructed from the same cycle database is entire, and its cycle expansion converges faster than exponentially. The fastest convergence is attained by the spectral determinant cycle expansion (23.19) and its derivatives. In this case the $\partial/\partial s$, $\partial/\partial \beta$ derivatives are computed recursively, by taking derivatives of the spectral determinant cycle expansion contributions (23.13) and (23.16).

The cycle averaging formulas are exact, and highly convergent for nice hyperbolic dynamical systems. An example of their utility is the cycle expansion formula for the Lyapunov exponent of example 23.1. Further applications of cycle expansions will be discussed in chapter 27.

### 23.5.3 Continuous vs. discrete mean return time

Sometimes it is convenient to compute an expectation value along a flow in continuous time, and sometimes it might be easier to compute it in discrete time, from a Poincaré return map. Return times (3.1) might vary wildly, and it is not at all clear that the continuous and discrete time averages are related in any simple way. As we shall now show, the relationship turns out to be both elegantly simple, and totally general.

The mean cycle period $\langle T \rangle_F$ fixes the normalization of the unit of time; it can be interpreted as the average near recurrence or the average first return time. For example, if we have evaluated a billiard expectation value $\langle a \rangle = \langle A \rangle_F/\langle T \rangle_F$ in terms of continuous time, and would like to also have the corresponding average

$$\langle a \rangle_\text{disc} = \langle A \rangle_F/\langle n \rangle_F$$

measured in discrete time, given by the number of reflections off billiard walls, the two averages are related by

$$\langle a \rangle_\text{disc} = \langle a \rangle (\langle T \rangle_F/\langle n \rangle_F),$$  

(23.28)

where $\langle n \rangle_F$ the average of the number of bounces $n_p$ along the cycle $p$ is given by (23.25).

**Example 23.1 Cycle expansion formula for Lyapunov exponents:** In sect. 20.5 we defined the Lyapunov exponent for a 1-dimensional map, relating it to the leading eigenvalue of an evolution operator, and promised to evaluate it. Now we are finally in position to deliver on our promise.

The cycle averaging formula (23.26) yields an exact explicit expression for the Lyapunov exponent in terms of prime cycles:

$$\lambda = \frac{1}{(2\pi)^2} \sum (-1)^{j+1} \frac{\log |\Lambda_{p_1}| + \cdots + \log |\Lambda_{p_n}|}{|\Lambda_{p_1} \cdots \Lambda_{p_n}|}.$$  

(23.29)

For a repeller, the $1/|\Lambda_p|$ weights are replaced by (27.10), the normalized measure weights $\exp(\gamma p)/|\Lambda_p|$, where $\gamma$ is the escape rate.

For 2-dimensional Hamiltonian flows such as our game of pinball (see example 22.3), there is only one expanding eigenvalue and (23.29) applies as written. However, in dimensions higher than one, a correct calculation of Lyapunov exponents requires a bit of sophistication.

### 23.6 Cycle expansions for finite alphabets

A finite transition graph like the one given in figure 17.3 (d) is a compact encoding of the transition matrix for a given subshift. It is a sparse matrix, and the associated determinant (18.32) can be written by inspection: it is the sum of all possible partitions of the graph into products of non-intersecting loops, with each loop carrying a minus sign:

$$\det (1 - T) = 1 - t_0 - t_011 - t_0011 - t_00011 + t_000011 + t_0000011$$  

(23.30)

The simplest application of this determinant is the evaluation of the topological entropy; if we set $t_p = e^\zeta p$, where $n_p$ is the length of the $p$-cycle, the determinant reduces to the topological polynomial (18.33).

The determinant (23.30) is exact for the finite graph figure 17.3 (e), as well as for the associated finite-dimensional transfer operator of example 20.4. For the associated (infinite dimensional) evolution operator, it is the beginning of the cycle expansion of the corresponding dynamical zeta function:

$$\frac{1}{\zeta} = 1 - t_0 - t_011 - t_0011 + t_00011 + t_000011$$

$$- (t_00011 - t_000011 + \cdots \text{curvatures}) \cdots$$  

(23.31)
CHAPTER 23. CYCLE EXPANSIONS

The cycles \( \Pi, 0001 \) and \( 001T \) are the fundamental cycles introduced in (23.8); they are not shadowed by any combinations of shorter cycles. All other cycles appear together with their shadows (for example, the \( t_{0001} - t_{0100} \) combination, see figure 1.12) and yield exponentially small corrections for hyperbolic systems. For cycle counting purposes, both \( L_a \) and the pseudo-cycle combination \( L_{ab} = L_{a+b} \) in (23.3) have the same weight \( e^{-\mu} \), so all curvature combinations \( t_{ab} - t_{a+b} \) vanish exactly, and the topological polynomial (18.17) offers a quick way of checking the fundamental part of a cycle expansion.

The splitting of cycles into the fundamental cycles and the curvature corrections depends on balancing long cycles \( t_{ab} \) against their pseudo-trajectory shadows \( L_{ab} \). If the \( ab \) cycle or either of the shadows \( a, b \) do not to exist, such curvature cancelation is unbalanced.

The most important lesson of the pruning of the cycle expansions is that prohibition of a finite subsequence imbalances the head of a cycle expansion and increases the number of the fundamental cycles in (23.8). Hence the pruned expansions are expected to start converging only after all fundamental cycles have been incorporated - in the last example, the cycles \( 1, 10, 10100, 101100 \). Without cycle expansions, no such crisp and clear cut definition of the fundamental set of scales is available.

Because topological zeta functions reduce to polynomials for finite grammars, only a few fundamental cycles exist and long cycles can be grouped into curvature combinations. For example, the fundamental cycles in exercise 11.1 are the three 2-cycles that bounce back and forth between two disks and the two 3-cycles that visit every disk. Of all cycles, the 2-cycles have the smallest Floquet exponent, and the 3-cycles the largest. It is only after these fundamental cycles have been included that a cycle expansion is expected to start converging smoothly, i.e., only for \( n \) larger than the lengths of the fundamental cycles are the curvatures \( \xi_n \) (in expansion (23.8)), a measure of the deviations between long orbits and their short cycle approximations, expected to fall off rapidly with \( n \).

23.7 Stability ordering of cycle expansions

There is never a second chance. Most often there is not even the first chance.

—John Wilkins

(C.P. Dettmann and P. Cvitanović)

We have judiciously deployed the 3-disk pinball, with its simple grammar, to motivate the periodic orbit theory. Most dynamical systems of interest, however, have infinite grammar, so at any order in \( z \) a cycle expansion may contain unmatched terms that do not fit neatly into the almost canceling curvature corrections. Similarly, for the intermittency, systems that we shall discuss in sect. 29.3.4, curvature corrections are not small in general, so again the cycle expansions may converge slowly. For such systems, schemes that collect the pseudocycle terms according to some other criterion than the topology of the flow may converge faster than expansions based on the topological length.

All chaotic systems exhibit some degree of shadowing, and a good truncation criterion should do its best to respect the shadowing as much as possible. If a long cycle is shadowed by two or more shorter cycles and the flow is smooth, the periods and the Floquet exponents will be additive in sense that the period of the longer cycle is approximately the sum of the shorter cycle periods. Similarly, as stability is multiplicative, shadowing is approximately preserved by including all terms with pseudo-cycle stability

\[
|A|_n \cdots |A|_1 \leq \Lambda_{\text{max}}
\]

(23.32)

and ignoring any pseudo-cycles that are less stable.

Two such schemes for ordering cycle expansions that approximately respect shadowing are truncations by the pseudocycle period and the stability ordering that we shall discuss here. In these schemes, a dynamical zeta function or a spectral determinant is expanded. One keeps all terms for which the period, action or stability for a combination of cycles (pseudo-cycles) is less than a given cutoff.

Settings in which stability ordering may be preferable to ordering by topological cycle length are the cases of bad grammar, of intermittency, and of partial cycle data sets.

23.7.1 Stability ordering for bad grammars

For generic flows it is often not clear what partition of state space generates the “optimal” symbolic dynamics. Stability ordering does not require understanding dynamics in such detail: if you can find the cycles, you can use stability-ordered cycle expansions. Stability truncation is thus easier to implement for a generic dynamical system than the curvature expansions (23.8) that rely on finite subshift approximations to a given flow.

Cycles can be detected numerically by searching a long trajectory for near recurrences. The long trajectory method for detecting cycles preferentially finds the least unstable cycles, regardless of their topological length. Another practical advantage of the method (in contrast to blind Newton method searches) is that it preferentially finds cycles in a given connected ergodic component of state space, ignoring isolated cycles or other ergodic regions elsewhere in state space.

Why should stability-ordered cycle expansions of a dynamical zeta function converge better than the crude trace formula (27.9), to be discussed in sect. 27.2? The argument has essentially already been laid out in sect. 18.6: in truncations that respect shadowing, most of the pseudo-cycles appear in shadowing combinations and nearly cancel, while only the relatively small subset affected by the increasingly long pruning rules is not shadowed. The error is typically of the order of \( 1/A \), which is smaller by a factor \( e^{hT} \) than the trace formula (27.9) error, where \( h \) is the entropy and \( T \) is the typical cycle length for cycles of stability A.
23.7.2 Smoothing

If most, but not all long cycles in a stability truncation are shadowed by shorter cycles, we say that the shadowing is partial. The breaking of exact shadowing cancellations deserves further comment. Any partial shadowing that may be present can be (partially) restored by smoothing the stability-ordered cycle expansions by replacing the \( 1/Λ \) weight for each term with the pseudo-cycle stability \( Λ = Λ_0 \cdots Λ_n \) by \( f(Λ)/Λ \). Here, \( f(Λ) \) decreases monotonically from \( f(0) = 1 \) to \( f(Λ_{\text{max}}) = 0 \). The lack of smoothing means we have a step function.

A typical “shadowing error” induced by the cutoff is due to two pseudo-cycles of stability \( Λ \) separated by \( ΔΛ \); the contributions of these pseudo-cycles are of opposite sign. Ignoring possible weighting factors, the magnitude of the resulting term is of order \( 1/ΔΛ \). With smoothing, one obtains an extra term of the form \( f'(Λ)ΔΛ/Λ \), which we want to minimize. A reasonable guess might be to keep \( f'(Λ)/Λ \) constant and as small as possible, so that

\[
f(Λ) = 1 - \left( \frac{Λ}{Λ_{\text{max}}} \right)^2.
\]

The results of a stability-ordered expansion (23.32) should always be tested for robustness by varying the cutoff \( Λ_{\text{max}} \). If this introduces significant variations, smoothing is probably necessary.

Résumé

A cycle expansion is a series representation of a dynamical zeta function, trace formula or a spectral determinant, with products in (22.11) expanded as sums over pseudo-cycles, which are products of the prime cycle weights \( t_ρ \).

If a flow is hyperbolic and has the topology of the Smale horseshoe (a subshift of finite type), dynamical zeta functions are holomorphic (have only poles in the complex s plane), the spectral determinants are entire, and the spectrum of the evolution operator is discrete. The situation is considerably more reassuring than what practitioners of quantum chaos fear; there is no ‘abscissa of absolute convergence’ and no ‘entropy barrier’, the exponential proliferation of cycles is no problem, spectral determinants are entire and converge everywhere, and the topology dictates the choice of cycles to be used in cycle expansion truncations.

In this case, the basic observation is that the motion in low-dimensional dynamical systems is organized around a few fundamental cycles, with the cycle expansion of the Euler product

\[
1/ζ = 1 - \sum f_τ - \sum_ν f_ν.
\]

regrouped into dominant fundamental contributions \( f_τ \) and decreasing curvature corrections \( f_ν \). The fundamental cycles \( f_τ \) have no shorter approximations; they are the ‘building blocks’ of the dynamics in the sense that all longer orbits can be approximately pieced together from them. A typical curvature contribution to \( f_ν \) is the difference of a long cycle \( [ab] \) and its shadowing approximation by shorter cycles \( [a] \) and \( [b] \), as in figure 1.12:

\[
Λ_0 + ΔΛ_0 = Λ_0(1 - ΔΛ_0/Λ_0).
\]

Orbits that follow the same symbolic dynamics, such as \([ab]\) and a ‘pseudo-cycle’ \([a][b]\), lie close to each other, have similar weights, and for increasingly long orbits the curvature corrections fall off rapidly. Indeed, for systems that satisfy the ‘axiom A’ requirements, such as the 3-disk billiard, curvature expansions converge very well.

Once a set of the shortest cycles has been found, and the cycle periods, stabilities, and integrated observable have been computed, the cycle averaging formulas such as (23.25) for the dynamical zeta function

\[
⟨a⟩ = \langle Α⟩_ζ/T_ζ, \quad \text{where for the zeta function expansions:}
\]

\[
⟨Α⟩_ζ = -\frac{1}{\partial β ζ} = \sum Λ_t t_τ, \quad ⟨T⟩_ζ = \frac{1}{\partial β ζ} = \sum Λ_t t_τ
\]

yield the expectation value of the observable \( a(x) \), i.e., the long time average over the chaotic non–wandering set.

Commentary

Remark 23.1 Alternative Periodic Orbit Theories.

Extraordinary how potent cheap music is.
— Noel Coward

There are no 'alternative periodic orbit theories'. There is only one ergodic theory, and periodic orbits are one aspect of it, just like there is only one quantum mechanics, and WKB is one way to gain insight into it. While the eigenfunctions of quantum evolution operators are smooth Hilbert space states, the eigenfunctions of deterministic evolution operators are highly singular, nowhere differentiable functions with support on fractal sets. The deterministic eigenstates of high-dimensional ergodic flows thus cannot be computed using the methods developed for quantum eigenstates, at least not without much further thought. The ergodic, singular ‘natural measure’ is harder (and in high-dimensional state space impossible) to construct numerically than its smooth quantum cousin, the ‘ground state’, and periodic orbits seem to be the way to do it. Were ergodic theory easy, ChaosBook.org and Gaspard monograph [A1.65] would have been a much breezier read.

In the vast and vastly uneven periodic orbit literature (should erroneous papers be cited?) one sometimes encounters the ‘escape-time weighting’,

\[
⟨a⟩_ρ = \frac{1}{⟨T⟩_ρ} = \frac{1}{\sum t_ρ t_τ}, \quad ⟨T⟩_ρ = \frac{1}{\sum t_ρ t_τ},
\]

(23.33)
where the $p$ sum goes over all known unstable periodic orbits, and sometimes also over judiciously chosen subsets of unstable equilibria. Here

$$\sum_j \lambda_j = \frac{1}{p} \ln \Lambda_p, \quad \Lambda_p = |\lambda_1 \lambda_2 \cdots \lambda_p|,$$  \hspace{1em} (23.34)

$T_p$ is the period of the prime periodic orbit $p$, $\lambda_j$ is the $j$th Floquet multiplier (4.7), $\Lambda_p$ is the product of the expanding multipliers $|\lambda_j| > 1$, $j = 1, \ldots, e$, and $\lambda_j$'s are the strictly positive Floquet exponents.

$$\sum_j \lambda_j$$

is the local escape rate from single repelling cycle $p$, of dimension 1/time, so one may interpret its inverse $\tau_p$ as "an estimate of the mean time spent by the system in vicinity of periodic orbit" $p$, $\tau_p$ is the Lyapunov time of cycle $p$, that is, the mean time it takes for the density of neighboring trajectories in an arbitrarily small ball centered around a point on the trajectory to decrease by factor $1/e$.

The 'escape-time weighting' was introduced in a rapid communication thusly: "Less unstable orbits must be weighted more heavily, so the attractor dimension is approximated by 'escape-time weighting' (23.33)." That's it: the 'derivation' in its entirety. Formula (23.33) is then asserted to approximate the time average $\langle a \rangle$ of observable $a(x)$ over the chaotic attractor in terms of

$$a_p = \frac{1}{p} \int_0^T \frac{dA}{f'}(u), \quad u_0 \in p,$$  \hspace{1em} (23.35)

averaged over each and every prime periodic orbit $p$ found in any computer exploration of a dynamical system's state space.

The enchantment with the escape-time weighting approach lies its charming simplicity. If one has a dynamical problem, and if one has a computer one has programmed to search for periodic orbits, and if the computer brings back a set of unstable periodic orbits, all one has to do is put $\tau_p$ and $a_p$ into the formula (23.33), and it returns a number - let's say $D = 9.0 \pm 0.1$, where the error one estimates somehow - which one then publishes.

The only drawback is that the 'formula' is wrong. (1) It comes from nowhere. (2) $\tau_p$ has dimension 1/time, but a 'weight' should be a dimensionless number, the likehood that an ergodic trajectory enters the neighborhood of the periodic orbit $p$. (3) $\sum_p$ is the sum over all unstable prime periodic orbits, regardless whether they belong to the ergodic component under investigation or dwell isolated in the Moon orbit. (4) The guess for the weight $\tau_p$ is clearly wrong, as any periodic orbit, no matter how long and unstable, has the comparable weight $\sum_j \lambda_j$, as long as its Lyapunovs (instability rate per unit time) are comparable; the Lyapunov time has nothing to do with the period of the particular cycle. For that there is a fix in the literature, with the Lyapunov time in (23.33) replaced by

$$\tau_p = T_p / \sum_j \lambda_j.$$  \hspace{1em} (23.36)

The fix is explained as follows: “it is reasonable also to suppose that orbits with longer periods must be weighted more heavily as they are longer and should provide a greater contribution to the total sum.” That’s it: the ‘derivation’ in its entirety. No less wrong.

The exact weight of the unstable prime periodic orbit $p$ (for level sum (21.6)) was given by Kadanoff and Tang [A1.32] in 1983. For the classical trace formula for flows (21.19) it is

$$T_p e^{T_p} \Lambda_p = T_p \Lambda_p, \quad \Lambda_p = \det \left( I - M_p \right)^{-1} e^{-T_p}.$$  \hspace{1em} (23.37)

where $s$ is the evolution operator eigenvalue, and $\beta$ is an auxiliary variable. It is determined by the dimensionless Floquet multipliers (eigenvalues of the periodic orbit’s monodromy matrix $M_p$) which grow/shrink exponentially with cycle period, not the Oseledec Lyapunov exponents or periodic orbit Floquet exponents which measure average expansion/contraction rate per unit time.

The exact cycle averaging formulas for the expectation value of the observable $a$, derived in chapters 19 to 22, have form

$$(a) = (A_p) / (T_p),$$  \hspace{1em} (23.38)

where the form of the periodic orbit sum $(\cdots)_p$ depends on whether it is computed from the trace formula (27.15), the dynamical zeta function (23.3), or the spectral determinant (23.15). This sum is never of the form (23.33).

Often one cares only about the leading long-time behavior, and for long periodic orbits approximates the denominator of (23.37) by the product of the expanding multipliers $\Lambda_p$ of the monodromy matrix $M_p$.

$$e^{-T_p} \Lambda_p \left[ \det \left( I - M_p \right) \right] \rightarrow t_p = e^{-T_p} \Lambda_p.$$  \hspace{1em} (23.39)

This weight seems to have been first used in 1987 by Auerbach et al. [A1.31], who computed an $n$th order estimate $t_n$, of the leading evolution operator eigenvalue $s$ from the sum of all periodic points $j$ of period $n$

$$1 = \sum_{j\in Fix\ p} t_j e^{\lambda j}, \quad t_j = e^{-\lambda j} \Lambda_p,$$  \hspace{1em} (23.40)

where $n$ is discrete time, and periodic points are fixed points of the $n$th iterate $j^n$. Even as it was written, the heuristics of this paper was superseded by the exact cycle expansions, first published in 1987 Cvitanović letter [A1.33].

Then there is in literature an ‘Alternative Periodic Orbit Theory’ so bold that one can only call it The Heresy: the conjecture is that if one looks carefully enough, there exists a single periodic orbit that captures all dynamical averages of a turbulent flow. This is so wrong that one is at loss what to say: there is NO such single periodic orbit. Instead, there is the product of the expanding multipliers $\Lambda_p$ given by Kadano and Tang [A1.32] in 1983. For the classical trace formula for flows (21.19) it is

$$T_p e^{T_p} \Lambda_p = T_p \Lambda_p,$$  \hspace{1em} (23.37)

where $s$ is the evolution operator eigenvalue, and $\beta$ is an auxiliary variable. It is determined by the dimensionless Floquet multipliers (eigenvalues of the periodic orbit’s monodromy matrix $M_p$) which grow/shrink exponentially with cycle period, not the Oseledec Lyapunov exponents or periodic orbit Floquet exponents which measure average expansion/contraction rate per unit time.

The exact cycle averaging formulas for the expectation value of the observable $a$, derived in chapters 19 to 22, have form

$$(a) = (A_p) / (T_p),$$  \hspace{1em} (23.38)

where the form of the periodic orbit sum $(\cdots)_p$ depends on whether it is computed from the trace formula (27.15), the dynamical zeta function (23.3), or the spectral determinant (23.15). This sum is never of the form (23.33).

Often one cares only about the leading long-time behavior, and for long periodic orbits approximates the denominator of (23.37) by the product of the expanding multipliers $\Lambda_p$ of the monodromy matrix $M_p$.

$$e^{-T_p} \Lambda_p \left[ \det \left( I - M_p \right) \right] \rightarrow t_p = e^{-T_p} \Lambda_p.$$  \hspace{1em} (23.39)

This weight seems to have been first used in 1987 by Auerbach et al. [A1.31], who computed an $n$th order estimate $t_n$, of the leading evolution operator eigenvalue $s$ from the sum of all periodic points $j$ of period $n$

$$1 = \sum_{j\in Fix\ p} t_j e^{\lambda j}, \quad t_j = e^{-\lambda j} \Lambda_p,$$  \hspace{1em} (23.40)

where $n$ is discrete time, and periodic points are fixed points of the $n$th iterate $j^n$. Even as it was written, the heuristics of this paper was superseded by the exact cycle expansions, first published in 1987 Cvitanović letter [A1.33].

Then there is in literature an ‘Alternative Periodic Orbit Theory’ so bold that one can only call it The Heresy: the conjecture is that if one looks carefully enough, there exists a single periodic orbit that captures all dynamical averages of a turbulent flow. This is so wrong that one is at loss what to say: there is NO such single periodic orbit. Instead, there is the well established theory that says how periodic orbits are to be used, and how many are needed to capture the hyperbolic parts of the non-wandering set with a desired accuracy. It is as elegant and systematic as Statistical Mechanics and Quantum Field Theory. Read ChaosBook.org. But who reads books nowadays?

Of course, if one picks at random a very long periodic orbit, one will get estimates as good as from an ergodic trajectory of comparable length, but then why make life hard by insisting on exact recurrence? When one starts out, The Heresy is one of the paths to enlightenment: Berry diplomatically writes “he found one orbit” in a bean to Gutzwiller [A1.17]. Indeed, in Gutzwiller first paper (1969) on anisotropic Kepler system, the one periodic orbit obtained by adiabatic deformation of a Kepler ellipse yielded 10% accuracy, which was great, as in those days it was generally believed that semiclascics should be bad for the ground state. Two years later Gutzwiller invented periodic orbit theory as a tool for physicists, applied it to the full anisotropic Kepler problem, and since then there is no turning back. Similarly, Kawahara [30.10] computed the first Navally Stokes periodic orbit solution embedded in turbulence, and observed that it gave rather accurate estimates of observables such as the dissipation rate.

The strangest thing about ‘Alternative Periodic Orbit Theories’ is that since introduction of zeta functions of Smale (1967), Gutzwiller (1969), Ruelle (1976) and their cycle
expansions (1987) there is no need for them whatsoever. Why would one guess an approximate periodic orbit weight when the exact weight is already known? It costs exactly the same to compute the exact spectral determinant as it costs to compute a wrong formula, both require the same periodic orbits, Floquet multipliers, periods, and cycle-averaged observables \( \alpha_p \). Go figure...

**Remark 23.2** Pseudo-cycle expansions, cumulant expansions. Bowen's introduction of shadowing e-pseudo-orbits [A1.70] was a significant contribution to Smale's theory. The expression 'pseudo-orbits' seems to have been introduced in Parry and Pollicott's 1983 paper [A1.49]. Following them, M. Berry [23.9] used the expression 'pseudo-orbits' and quantum chaosology. Cycle and curvature expansions of dynamical zeta functions and spectral determinants in terms of pseudo-cycles were introduced in refs. [2, A1.30]. Some literature [25.18] refers to pseudo-orbits as 'composite orbits', and to cycle expansions as 'Drichtlet series' (see also appendix A20.5 and remark A20.11). To statistical mechanicians, curvature expansions are very reminiscent of cumulant expansions. Indeed, (23.16) is the standard Plemelj-Smithies cumulant formula for the Fredholm determinant. A new aspect, not reminiscent of statistical mechanics, is that in cycle expansions each \( Q_n \) coefficient is expressed as a sum over exponentially many cycles.

Going from \( N_r = N^r \) periodic points of period \( r \) to \( M_r \) prime cycles reduces the number of computations from \( N_r \) to \( M_r = N^{r-1} / n \). The use of discrete symmetries (chapter 25) reduces the number of \( n \)-th level terms by another factor. While reformulating the theory from trace (21.24) to cycle expansion (23.8) does not eliminate exponential growth in the number of cycles, in practice only the shortest cycles are used, and the reduction in computational labor for these cycles can be significant.

**Remark 23.3** Shadowing cycle-by-cycle. A glance at the low order curvatures in table 23.1 leads to the temptation to associate curvatures to individual cycles, such as \( \zeta_{0010} = \zeta_{0001} = \zeta_{0011} \). Such combinations tend to be numerically small (see, for example, ref. [A1.27], table 1). However, splitting \( \zeta_{n} \) into individual cycle curvatures is not possible in general [23.12]; the first example of such ambiguity in the binary cycle expansion is given by the \( \zeta_{0001} - \zeta_{00010} \) 0 ↔ 1 symmetric pair of 6-cycles; the counterterm \( t_{001+01} \) in table 23.1 is shared by these two cycles.

**Remark 23.4** Escape rates. A lucid introduction to escape from repellors is given by Kadanoff and Tang [A1.32]. For a review of transient chaos see refs. [27.12, 27.13]. The \( \zeta \)-function formulation is given by Ruelle [A1.22] and W. Parry and M. Pollicott [A1.49] and discussed in ref. [A1.33]. Altmann and Tel [27.16] give a detailed study of escape rates, with citations to more recent literature.

**Remark 23.5** Stability ordering. The stability ordering was introduced by Dahlqvist andRussberg [A1.46, A1.47] in a study of chaotic dynamics for the \((x^2)^{1/2}\) potential. The presentation here runs along the lines of Dettmann and Morriss [A1.48] for the Lorentz gas, which is hyperbolic but with highly pruned symbolic dynamics, and Dettmann and Cvitanović [23.16] for a family of intermittent maps. In the applications discussed in the above papers, stability ordering yields a considerable improvement over topological length ordering. In quantum chaos applications, cycle expansion cancelations are affected by the phases of pseudo-cycles (their actions), hence period or action ordering rather than stability is frequently employed.

**Remark 23.6** Desymmetrized cycle expansions. The 3-disk cycle expansions (25.54) might be useful for cross-checking purposes, but, as we shall see in chapter 25, they are not recommended for actual computations, as the factorized zeta functions yield much better convergence.

### 23.8 Examples

**Example 23.2** Newton algorithm for determining the evolution operator eigenvalues:

- Cycle expansions of spectral determinants can be used to compute a set of leading eigenvalues of the evolution operator. A convenient way to search for these is by plotting either the absolute magnitude \(|\det (s - \Lambda)|\) or the phase of spectral determinants and dynamical zeta functions as functions of the complex variable \( s \). The eye is guided to the zeros of spectral determinants and dynamical zeta functions by means of complex \( s \) plane contour plots, with different intervals of the absolute value of the function under investigation assigned different colors; zeros emerge as centers of elliptic neighborhoods of rapidly changing colors. Detailed scans of the whole area of the complex \( s \) plane under investigation and searches for the zeros of spectral determinants, figure 23.1, reveal complicated patterns of resonances even for something as simple as the 3-disk game of pinball. With a good starting guess (such as the location of a zero suggested by the complex \( s \) scan of figure 23.1), a zero \( 1/(s(x)) = 0 \) can now be determined by standard numerical methods, such as the iterative Newton algorithm (7.3), with the \( n \)-th Newton estimate given by

\[
\xi_{n+1} = \xi_n - \frac{\partial}{\partial \xi} \left( \frac{1}{\det (s - \Lambda)} \right) \xi_n \quad \xi_0 = \frac{1}{\det (s - \Lambda)}.
\]

The denominator (\( \det \)) is required for Newton iteration and is given by cycle expansion (23.25). We need to evaluate it anyhow, as (\( \det \)) is needed for the cycle averaging formulas.

**Example 23.3** Cycle expansion for the mean cycle period:

For example, for the complete binary symbolic dynamics the mean cycle period \((T)_c\) is given by

\[
(T)_c = \frac{T_0}{|N_0|} + \frac{T_1}{|N_1|} + \left( \frac{T_{00}}{|N_{00}|} - \frac{T_{0} + T_1}{|N_{0}|} \right) + \left( \frac{T_{01}}{|N_{01}|} - \frac{T_{0} + T_1}{|N_{0}|} \right) + \ldots
\]

Note that the cycle expansions for averages are grouped into the same shadowing combinations as the dynamical zeta function cycle expansion (23.8), with nearby pseudo-cycles nearly canceling each other.
Exercises

23.1. Cycle expansions. Write programs that implement binary symbolic dynamics cycle expansions for (a) dynamical zeta functions, (b) spectral determinants. Combined with the cycles computed for a 2-branch repeller or a 3-disk system they will be useful in the problems below.

23.2. Escape rate for a 1-dimensional repeller. (continuation of exercise 20.2 - easy, but long) Consider again the quadratic map (20.48)

\[ f(x) = Ax(1-x) \]

on the unit interval. In order to be definitive, take either \( A = 9/2 \) or \( A = 6 \). Describing the itineraries of any trajectory by the binary alphabet \( \{0,1\} \) ("0" if the iterate is in the first half of the interval and "1" if it is in the second half), we have a repeller with a complete binary symbolic dynamics.

(a) Sketch the graph of \( f \) and determine its two fixed points \( \bar{0} \) and \( \bar{1} \), along with their stabilities.

(b) Sketch the two branches of \( f^{-1} \). Determine all the prime cycles up to topological length 4 using your calculator and backwards iteration of \( f \) (see sect. 7.1.1).

(c) Determine the leading zero of the zeta function (22.11) using the weights \( t_k = \pi k / |\Lambda_k| \), where \( |\Lambda_k| \) is the stability of the \( k \)-cycle.

(d) Show that for \( A = 9/2 \) the escape rate of the repellor is 0.361509... using the spectral determinant with the same cycle weight. If you have taken \( A = 6 \), show instead that the escape rate is in 0.83149298... Compare the coefficients of the spectral determinant and the zeta function cycle expansions. Which expansion converges faster?

(Per Rosenqvist)

23.3. Escape rate for the Ulam map. (Medium; repeat of exercise 16.1) We will try to compute the escape rate for the Ulam map (14.21)

\[ f(x) = 4x(1-x) \]

using the method of cycle expansions. The answer should be zero, as nothing escapes.

(a) Compute a few of the stabilities for this map. Show that \( A_0 = 4 \), \( A_1 = -2 \), \( A_{00} = -4 \), \( A_{01} = -8 \) and \( A_{000} = 8 \).

(b) Show that

\[ \Lambda_{m,n} = \pm 2^n \]

and determine a rule for the sign.

(c) (Hard) Compute the dynamical zeta function for this system

\[ \chi^{-1} = 1 - t_0 - t_1 - (t_0 - t_0 t_1) - \ldots \]

Note that the convergence as a function of the truncation cycle length is slow. Try to fix that by treating the \( \Lambda_{m,n} \) as 4 cycle separately. (continued as exercise 23.11)

23.4. Pinball escape rate, semi-analytical. Estimate the 3-disk pinball escape rate for \( R : a = 6 \) by substituting analytical cycle stabilities and periods (see exercise 16.6 and exercise 16.7) into the appropriate binary cycle expansion. Compare your result with the numerical estimate exercise 20.3.

23.5. Pinball escape rate, from numerical cycles. Compute the escape rate for the 3-disk pinball with \( R : a = 6 \) by substituting the list of numerically computed cycle stabilities of exercise 16.5 into the binary cycle expansion.

23.6. Pinball resonances in the complex plane. Plot the logarithm of the absolute value of the dynamical zeta function and/or the spectral determinant cycle expansion (23.5) as contour plots in the complex plane. Do you find zeros other than the one corresponding to the complex plane? Do you see evidence for a finite radius of convergence for either cycle expansion?

23.7. Counting the 3-disk punctions. (continuation of exercise 18.12) Show that the number of terms in the 3-disk pinball curvature expansion (25.53) is given by

\[ \Pi_j (1 + t_j) = \frac{1 - 3^{m} - 2^{m} - 1}{1 - 3^{m} - 2^{m}} \]

where \( t_j = 3^{m} \) (6 + 12 + 2c).

This means that, for example, \( c_0 \) has a total of 20 terms, in agreement with the explicit 3-disk cycle expansion (25.54).
