Chapter 37

Relaxation for cyclists

Cycles, i.e., solutions of the periodic orbit condition (17.1)

$$f^{t+T}(x) = f^t(x)\,, \qquad T > 0 \tag{37.1}$$

are prerequisite to chapters 14 and 15 evaluation of spectra of classical evolution operators, and, as we shall see in chapter 36, the semiclassical approximations to quantum evolution operators. Chapter 17 offered an introductory, hands-on guide to extraction of periodic orbits by means of the Newton-Raphson method. Here we take a very different tack, drawing inspiration from variational principles of classical mechanics, and path integrals of quantum mechanics.

emphasize importance of equilibrium points!

In sect. 17.2.1 we converted orbits unstable forward in time into orbits stable backwards in time. Indeed, all methods for finding unstable cycles are based on the idea of constructing a new dynamical system such that (*i*) the position of the cycle is the same for the original system and the transformed one, (*ii*) the unstable cycle in the original system is a stable cycle of the transformed system.

The Newton-Raphson method for determining a fixed point x_* for a map $x' = f(x)$ is an example. The method replaces iteration of $f(x)$ by iteration of the Newton-Raphson map (17.5)

$$x'_i = g_i(x) = x_i - \left(\frac{1}{M(x) - \mathbf{1}}\right)_{ij} (f(x) - x)_j\,. \tag{37.2}$$

A fixed point x_* for a map $f(x)$ is also a fixed point of $g(x)$, indeed a super-stable fixed point since $\partial g_i(x_*)/\partial x_j = 0$. This makes the convergence to the fixed point super-exponential.

We also learned in chapter 17 that methods that start with initial guesses for a number of points along a cycle are considerably more robust

cost function
periodic!orbit extraction!relaxation algorithm
relaxation algorithm
gradient algorithm
Henon@H"enon!map
map!H"enon

and safer than searches based on direct solution of the fixed-point condition (37.1). The relaxation (or variational) methods that we shall now describe take this multipoint approach to its logical extreme, and start by a guess of not a few points along a periodic orbit, but a guess of the entire orbit.

The idea is to make an informed rough guess of what the desired periodic orbit looks like globally, and then use variational methods to drive the initial guess toward the exact solution. Sacrificing computer memory for robustness of the method, we replace a guess that a *point* is on the periodic orbit by a guess of the *entire orbit*. And, sacrificing speed for safety, in sect. 37.1 we replace the Newton-Raphson *iteration* by a fictitious time *flow* that minimizes a cost function computed as deviation of the approximate flow from the true flow along a loop approximation to a periodic orbit.

If you have some insight into the topology of the flow and its symbolic dynamics, or have already found a set of short cycles, you might be able to construct an initial approximation to a longer cycle p as a sequence of N points $(\tilde{x}_1^{(0)}, \tilde{x}_2^{(0)}, \cdots, \tilde{x}_N^{(0)})$ with the periodic boundary condition $\tilde{x}_{N+1} = \tilde{x}_1$. Suppose you have an iterative method for improving your guess; after k iterations the cost function

normalize to take account of a continuous time limit?

$$F^2(\tilde{x}^{(k)}) = \sum_i^N \left(\tilde{x}_{i+1}^{(k)} - f(\tilde{x}_i^{(k)})\right)^2 \tag{37.3}$$

or some other more cleverly constructed function (for classical mechanics - action) is a measure of the deviation of the kth approximate cycle from the true cycle. This observation motivates variational approaches to determining cycles.

We give here three examples of such methods, two for maps, and one for billiards. In sect. 37.1 we start out by converting a problem of finding an unstable fixed point of a map into a problem of constructing a differential flow for which the desired fixed point is an attracting equilibrium point. Solving differential equations can be time intensive, so in sect. 37.2 we replace such flows by discrete iterations. In sect. 37.3 we show that for $2D$-dimensional billiard flows variation of D coordinates (where D is the number of Hamiltonian degrees of freedom) suffices to determine cycles in the full $2D$-dimensional phase space.

preface with crete02.tex?

37.1 Fictitious time relaxation

(O. Biham, C. Chandre and P. Cvitanović)

The relaxation (or gradient) algorithm for finding cycles is based on the observation that a trajectory of a map such as the Hénon map (3.15),

$$\begin{aligned} x_{i+1} &= 1 - ax_i^2 + by_i \\ y_{i+1} &= x_i\,, \end{aligned} \tag{37.4}$$

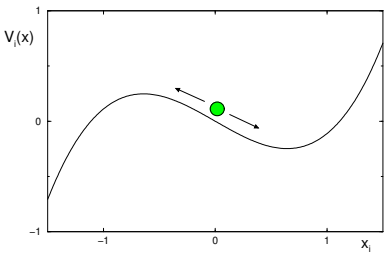

Figure 37.1: "Potential" $V_i(x)$ (37.7) for a typical point along an inital guess trajectory. For $\sigma_i = +1$ the flow is toward the local maximum of $V_i(x)$, and for $\sigma_i = -1$ toward the local minimum. A large deviation of x_i's is needed to destabilize a trajectory passing through such local extremum of $V_i(x)$, hence the basin of attraction is expected to be large.

is a stationary solution of the relaxation dynamics defined by the flow

$$\frac{dx_i}{d\tau} = v_i, \quad i = 1, \ldots, n \tag{37.5}$$

for any vector field $v_i = v_i(x)$ which vanishes on the trajectory. Here τ is a "fictitious time" variable, unrelated to the dynamical time (in this example, the discrete time of map iteration). As the simplest example, take v_i to be the deviation of an approximate trajectory from the exact 2-step recurrence form of the Hénon map (3.16)

$$v_i = x_{i+1} - 1 + ax_i^2 - bx_{i-1}. \tag{37.6}$$

For fixed x_{i-1}, x_{i+1} there are two values of x_i satisfying $v_i = 0$. These solutions are the two extremal points of a local "potential" function (no sum on i)

cannot write a global potential function $V(x) = \sum_i V_i(x)$!

$$v_i = \frac{\partial}{\partial x_i} V_i(x)\,, \qquad V_i(x) = x_i(x_{i+1} - bx_{i-1} - 1) + \frac{a}{3}x_i^3\,. \tag{37.7}$$

Assuming that the two extremal points are real, one is a local minimum of $V_i(x)$ and the other is a local maximum. Now here is the idea; replace (37.5) by

$$\frac{dx_i}{d\tau} = \sigma_i v_i, \quad i = 1, \ldots, n, \tag{37.8}$$

where $\sigma_i = \pm 1$.

The modified flow will be in the direction of the extremal point given by the local maximum of $V_i(x)$ if $\sigma_i = +1$ is chosen, or in the direction of the one corresponding to the local minimum if we take $\sigma_i = -1$. This is not quite what happens in solving (37.8) - all x_i and $V_i(x)$ change at each integration step - but this is the observation that motivates the method. The differential equations (37.8) then drive an approximate initial guess toward the exact trajectory. A sketch of the landscape in which x_i converges towards the proper fixed point is given in figure 37.1. As the "potential" function (37.7) is not bounded for a large $|x_i|$, the flow diverges for initial

guesses which are too distant from the true trajectory. However, the basin of attraction of initial guesses that converge to a given cycle is nevertheless very large, with the spread in acceptable initial guesses for figure 37.1 of order 1, in contrast to the exponential precision required of initial guesses by the Newton-Raphson method.

Example 37.1 Hénon map cycles. *Our aim in this calculation is to find all periodic orbits of period n for the Hénon map (37.4), in principle at most 2^n orbits. We start by choosing an initial guess trajectory $(x_1, x_2, \cdots, x_n)$ and impose the periodic boundary condition $x_{n+1} = x_1$. The simplest and a rather crude choice of the initial condition in the Hénon map example is $x_i = 0$ for all i. In order to find a given orbit one sets $\sigma_i = -1$ for all iterates i which are local minima of $V_i(x)$, and $\sigma_i = 1$ for iterates which are local maxima. In practice one runs through a complete list of prime cycles, such as the table 11.1. The real issue for all searches for periodic orbits, this one included, is how large is the basin of attraction of the desired periodic orbit? There is no easy answer to this question, but empirically it turns out that for the Hénon map such initial guess almost always converges to the desired trajectory as long as the initial $|x|$ is not too large compared to $1/\sqrt{a}$. Figure 37.1 gives some indication of a typical basin of attraction of the method (see also figure 37.3).*

⇓PRELIMINARY
find this? for table 37.1
⇑PRELIMINARY

(Work through exercise ??). The calculation is carried out by solving the set of n ordinary differential equations (37.8) using a simple Runge-Kutta method with a relatively large step size ($h = 0.1$) until $|v|$ becomes smaller than a given value ε (in a typical calculation $\varepsilon \sim 10^{-7}$). Empirically, in the case that an orbit corresponding to the desired itinerary does not exist, the initial guess escapes to infinity since the "potential" $V_i(x)$ grows without bound.

37.3
page 707

Applied to the Hénon map at the Hénon's parameters choice $a = 1.4$, $b = 0.3$, the method has yielded all periodic orbits to periods as long as $n = 28$, as well as selected orbits up to period $n = 1000$. All prime cycles up to period 10 for the Hénon map, $a = 1.4$ and $b = 0.3$, are listed in table 37.1. The number of unstable periodic orbits for periods $n \leq 28$ is given in table 37.2. Comparing this with the list of all possible 2-symbol alphabet prime cycles, table 11.1, we see that the pruning is quite extensive, with the number of cycle points of period n growing as $e^{0.4645 \cdot n} = (1.592)^n$ rather than as 2^n.

recheck 0.4645, 1.592

contruct grammar

As another example we plot all unstable periodic points up to period $n = 14$ for $a = 1.8$, $b = 0.3$ in figure 37.2. Comparing this repelling set with the strange attractor for the Hénon's parameters figure 3.5, we note the existence of gaps in the set, cut out by the preimages of the escaping regions.

replot figure 37.2 with the correct scale for (37.4), with x_{t-1} horizontally, x_t vertically (so it looks like a parabola, becomes on in the $b \to 0$ limit)

☞ remark 37.2

In practice, the relaxation flow (37.8) finds (almost) all periodic orbits which exist and indicates which ones do not. For the Hénon map the method enables us to calculate almost all unstable cycles of essentially any desired length and accuracy.

Table 37.1: All prime cycles up to period 10 for the Hénon map, $a = 1.4$ and $b = 0.3$. The columns list the period n_p, the itinerary (defined in remark 37.4), a cycle point (y_p, x_p), and the cycle Lyapunov exponent $\lambda_p = \ln|\Lambda_p|/n_p$. While most of the cycles have $\lambda_p \approx 0.5$, several significantly do not. The $\overline{0}$ cycle point is very unstable, isolated and transient fixed point, with no other cycles returning close to it. At period 13 one finds a pair of cycles with exceptionally low Lyapunov exponents. The cycles are close for most of the trajectory, differing only in the one symbol corresponding to two cycle points straddle the (partition) fold of the attractor. As the system is not hyperbolic, there is no known lower bound on cycle Lyapunov exponents, and the Hénon's strange "attractor" might some day turn out to be nothing but a transient on the way to a periodic attractor of some long period.

Table 37.2: The number of unstable periodic orbits of the Hénon map for $a = 1.4$, $b = 0.3$, of all periods $n \leq 28$. M_n is the number of prime cycles of length n, and N_n is the total number of periodic points of period n (including repeats of shorter prime cycles).

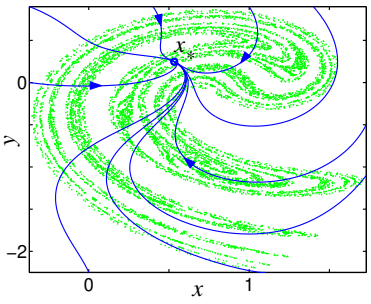

Figure 37.3: Typical trajectories of the vector field (37.9) for the stabilization of a hyperbolic fixed point of the Ikeda map (37.11) located at $(x, y) \approx (0.53275, 0.24689)$. The circle indicates the position of the fixed point. Note that the basin of attraction of this fixed point is large, larger than the entire Ikeda attractor.

The idea of the relaxation algorithm illustrated by the above Hénon map example is that instead of searching for an unstable periodic orbit of a map, one searches for a stable attractor of a vector field. More generally, consider a d-dimensional map $x' = f(x)$ with a hyperbolic fixed point x_*. Any fixed point x_* is by construction an equilibrium point of the fictitious time flow

$$\frac{dx}{d\tau} = f(x) - x. \tag{37.9}$$

If all eigenvalues of the fundamental matrix $J(x_*) = Df(x_*)$ have real parts smaller than unity, then x_* is a stable equilibrium point of the flow.

If some of the eigenvalues have real parts larger than unity, then one needs to modify the vector field so that the corresponding directions of the flow are turned into stable directions in a neighborhood of the fixed point. In the spirit of (37.8), modify the flow by

$$\frac{dx}{d\tau} = \mathbf{C}\,(f(x) - x)\ , \tag{37.10}$$

where $\mathbf{C}$ is a $[d \times d]$ invertible matrix. The aim is to turn x_* into a stable equilibrium point of the flow by an appropriate choice of $\mathbf{C}$. It can be shown that a set of permutation / reflection matrices with one and only one non-vanishing entry ± 1 per row or column (for d-dimensional systems, there are $d!2^d$ such matrices) suffices to stabilize any fixed point. In practice, one chooses a particular matrix $\mathbf{C}$, and the flow is integrated. For each choice of $\mathbf{C}$, one or more hyperbolic fixed points of the map may turn into stable equilibria of the flow.

☞ appendix H.2

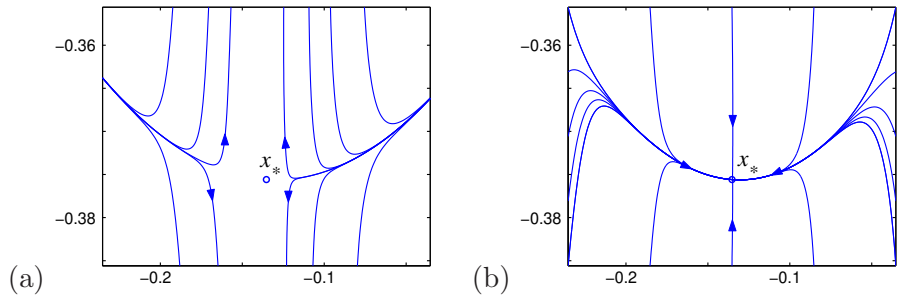

Figure 37.4: Typical trajectories of the vector field (37.10) for a hyperbolic fixed point $(x, y) \approx (-0.13529, -0.37559)$ of f^3, where f is the Ikeda map (37.11). The circle indicates the position of the fixed point. For the vector field corresponding to (a) $\mathbf{C} = \mathbf{1}$, x_* is a hyperbolic equilibrium point of the flow, while for (b) $\mathbf{C} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$, x_* is an attracting equilibrium point.

Example 37.2 Ikeda map: *We illustrate the method with the determination of the periodic orbits of the Ikeda map:*

$$\begin{aligned} x' &= 1 + a(x\cos w - y\sin w) \\ y' &= a(x\sin w + y\cos w) \\ \text{where}\quad w &= b - \frac{c}{1+x^2+y^2}\,, \end{aligned} \tag{37.11}$$

with $a = 0.9$, $b = 0.4$, $c = 6$. The fixed point x_* is located at $(x, y) \approx (0.53275, 0.24689)$, with eigenvalues of the fundamental matrix $(\Lambda_1, \Lambda_2) \approx (-2.3897, -0.3389)$, so the flow is already stabilized with $\mathbf{C} = \mathbf{1}$. Figure 37.3 depicts the flow of the vector field around the fixed point x_*.

In order to determine x_*, one needs to integrate the vector field (37.9) forward in time (the convergence is exponential in time), using a fourth order Runge-Kutta or any other integration routine.

In contrast, determination of the 3-cycles of the Ikeda map requires nontrivial $\mathbf{C}$ matrices, different from the identity. Consider for example the hyperbolic fixed point $(x, y) \approx (-0.13529, -0.37559)$ of the third iterate f^3 of the Ikeda map. The flow of the vector field for $\mathbf{C} = \mathbf{1}$, Figure 37.4 (a), indicates a hyperbolic equilibrium point, while for $\mathbf{C} = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$ the flow of the vector field, figure 37.4 (b) indicates that x_* is an attracting equilibrium point, reached at exponential speed by integration forward in time.

The generalization from searches for fixed points to searches for cycles is straightforward. In order to determine a prime cycle $x = (x_1, x_2, \ldots, x_n)$ of a d-dimensional map $x' = f(x)$, we modify the multipoint shooting method of sect. 17.4.1, and consider the nd-dimensional vector field

$$\frac{dx}{d\tau} = \mathbf{C}\,(f(x) - x)\ , \tag{37.12}$$

where $f(x) = (f(x_n), f(x_1), f(x_2), \ldots, f(x_{n-1}))$, and $\mathbf{C}$ is an invertible $[nd \times nd]$ matrix. For the Hénon map, it is sufficient to consider a set of 2^n diagonal matrices with eigenvalues ± 1. Risking a bit of confusion, we denote by x, $f(x)$ both the d-dimensional vectors in (37.10), and nd-dimensional vectors in (37.12), as the structure of the equations is the same.

37.2 Discrete iteration relaxation method

add to the coauthors list

(C. Chandre, F.K. Diakonos and P. Schmelcher)

The problem with the Newton-Raphson iteration (37.2) is that it requires very precise initial guesses. For example, the nth iterate of a unimodal map has as many as 2^n periodic points crammed into the unit interval, so determination of all cycles of length n requires that the initial guess for each one of them has to be accurate to roughly 2^{-n}. This is not much of a problem for 1-dimensional maps, but making a good initial guess for where a cycle might lie in a d-dimensional state space can be a challenge.

Emboldened by the success of the cyclist relaxation trick (37.8) of manually turning instability into stability by a sign change, we now (*i*) abandon the Newton-Raphson method altogether, (*ii*) abandon the continuous fictitious time flow (37.9) with its time-consuming integration, replacing it by a map g with a larger basin of attraction (not restricted to a linear neighborhood of the fixed point). The idea is to construct a very simple map g, a linear transformation of the original f, for which the fixed point is stable. We replace the fundamental matrix prefactor in (37.2) (whose inversion can be time-consuming) by a constant matrix prefactor

$$x' = g(x) = x + \Delta\tau \mathbf{C}(f(x) - x), \tag{37.13}$$

where $\Delta\tau$ is a positive real number, and $\mathbf{C}$ is a $[d\times d]$ permutation and reflection matrix with one and only one non-vanishing entry ± 1 per row or column. A fixed point of f is also a fixed point of g. Since $\mathbf{C}$ is invertible, the inverse is also true.

This construction is motivated by the observation that for small $\Delta\tau \to d\tau$ the map (37.13) is the Euler method for integrating the modified flow (37.10), with the integration step $\Delta\tau$.

The argument why a suitable choice of matrix $\mathbf{C}$ can lead to the stabilization of an unstable periodic orbit is similar to the one used to motivate the construction of the modified vector field in sect. 37.1. Indeed, the flow (37.8) is the simplest example of this method, with the infinitesimal fictitious time increment $\Delta\tau \to d\tau$, the infinitesimal coordinate correction $(x - x') \to dx_i$, and the $[n\times n]$ diagonal matrix $\mathbf{C} \to \sigma_i = \pm 1$.

For a given fixed point of $f(x)$ we again chose a $\mathbf{C}$ such that the flow in the expanding directions of $M(x_*)$ is turned into a contracting flow. The aim is to stabilize x_* by a suitable choice of $\mathbf{C}$. In the case where the map has multiple fixed points, the set of fixed points is obtained by changing the matrix $\mathbf{C}$ (in general different for each unstable fixed point) and varying initial conditions for the map g. For example, for 2-dimensional dissipative maps it can be shown that the 3 matrices

☞ remark 37.3

$$\mathbf{C} \in \left\{ \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \right\}$$

appendix H.2

suffice to stabilize all kinds of possible hyperbolic fixed points.

If $\Delta\tau$ is chosen sufficiently small, the magnitude of the eigenvalues of the fixed point x_* in the transformed system are smaller than one, and one has a stable fixed point. However, $\Delta\tau$ should not be chosen too small: Since the convergence is geometrical with a ratio $1-\alpha\Delta\tau$ (where the value of constant α depends on the stability of the fixed point in the original system), small $\Delta\tau$ can slow down the speed of convergence. The critical value of $\Delta\tau$, which just suffices to make the fixed point stable, can be read off from the quadratic equations relating the stability coefficients of the original system and those of the transformed system. In practice, one can find the optimal $\Delta\tau$ by iterating the dynamical system stabilized with a given $\mathbf{C}$ and $\Delta\tau$. In general, all starting points converge on the attractor provided $\Delta\tau$ is small enough. If this is not the case, the trajectory either diverges (if $\Delta\tau$ is far too large) or it oscillates in a small section of the state space (if $\Delta\tau$ is close to its stabilizing value).

The search for the fixed points is now straightforward: A starting point chosen in the global neighborhood of the fixed point iterated with the transformed dynamical system g converges to the fixed point due to its stability. Numerical investigations show that the domain of attraction of a stabilized fixed point is a rather extended connected area, by no means confined to a linear neighborhood. At times the basin of attraction encompasses the complete state space of the attractor, so one can be sure to be within the attracting basin of a fixed point regardless of where on the on the attractor on picks the initial condition.

The step size $|g(x)-x|$ decreases exponentially when the trajectory approaches the fixed point. To get the coordinates of the fixed points with a high precision, one therefore needs a large number of iterations for the trajectory which is already in the linear neighborhood of the fixed point. To speed up the convergence of the final part of the approach to a fixed point we recommend a combination of the above approach with the Newton-Raphson method (37.2).

The fixed points of the nth iterate f^n are cycle points of a cycle of period n. If we consider the map

$$x' = g(x) = x + \Delta\tau\mathbf{C}(f^n(x) - x)\,, \tag{37.14}$$

the iterates of g converge to a fixed point provided that $\Delta\tau$ is sufficiently small and $\mathbf{C}$ is a $[d\times d]$ constant matrix chosen such that it stabilizes the flow. As n grows, $\Delta\tau$ has to be chosen smaller and smaller. In the case of the Ikeda map example 37.2 the method works well for $n \leq 20$. As in (37.12), the multipoint shooting method is the method of preference for determining longer cycles. Consider $x = (x_1, x_2, \ldots, x_n)$ and the nd-dimensional map

$$x' = f(x) = (f(x_n), f(x_1), \ldots, f(x_{n-1}))\,.$$

Maupertuis, P.L.M. de
least action principle

Determining cycles with period n for the d-dimensional f is equivalent to determining fixed points of the multipoint dn-dimensional f. The idea is to construct a matrix $\mathbf{C}$ such that the fixed point of f becomes stable for the map:

$$x' = x + \Delta\tau \mathbf{C}(f(x) - x),$$

where $\mathbf{C}$ is now a $[nd \times nd]$ permutation/reflection matrix with only one non-zero matrix element ± 1 per row or column. For any given matrix $\mathbf{C}$, a certain fraction of the cycles becomes stable and can be found by iterating the transformed map which is now a nd dimensional map.

From a practical point of view, the main advantage of this method compared to the Newton-Raphson method is twofold: (*i*) the stability matrix of the flow need not be computed, so there is no large matrix to invert, simplifying considerably the implementation, and (*ii*) empirical basins of attractions for individual $\mathbf{C}$ are much larger than for the Newton-Raphson method. The price is a reduction in the speed of convergence.

37.3 Least action method

(P. Dahlqvist)

The methods of sects. 37.1 and 37.2 are somewhat *ad hoc*, as for general flows and iterated maps there is no fundamental principle to guide us in chosing the cost function, such as (37.3), to vary.

include Per's section 5.5.

For Hamiltonian dynamics, we are on much firmer ground; Maupertuis least action principle. You yawn your way through it in every mechanics course - Maupertuis believed that the principle provided a proof of the existence of God - but as we shall now see, it is a very hands-on numerical method for finding cycles.

Indeed, the simplest and numerically most robust method for determining cycles of planar billiards is given by the principle of least action, or equivalently, by extremizing the length of an approximate orbit that visits a given sequence of disks. In contrast to the multipoint shooting method of sect. 17.4.1 which requires variation of $2N$ phase space points, extremization of a cycle length requires variation of only N bounce positions s_i.

The problem is to find the extremum values of cycle length $L(s)$ where $s = (s_1, \ldots, s_N)$, that is find the roots of $\partial_i L(s) = 0$. Expand to first order

$$\partial_i L(s_0 + \delta s) = \partial_i L(s_0) + \sum_j \partial_i \partial_j L(s_0) \delta s_j + \ldots$$

37.4 Newton Descent in Loop Space

⇓PRELIMINARY

For a flow described by a set of ODEs, multipoint shooting method of ?? can be quite efficient. However, multipoint shooting requires a set of state space Poincaré sections such that an orbit leaving one section reaches

link refsects:MultDimDescent

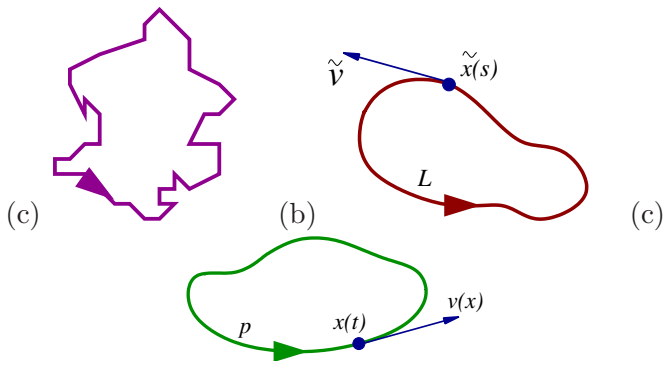

Figure 37.5: (a) A continuous path; (b) a loop L with its tangent velocity vector $\tilde{v}$; (c) a periodic orbit p defined by the vector field $v(x)$.

the next one in a qualitatively predictable manner, without traversing other sections along the way. In turbulent, high-dimensional flows such sequences of sections are hard to come by. One cure for this ill might be a large set of Poincaré sections, with the intervening flight segments short and controllable. Here we shall take another path, and discard fixed Poincaré sections altogether.

Emboldened by success of methods such as the multipoint shooting (which eliminates the long-time exponential instability by splitting an orbit into a number of short segments, each with a controllable expansion rate) and the cyclist relaxation methods of sect.?! (which replace map iteration by a contracting flow whose attractor is the desired periodic orbit of the original iterative dynamics), we now describe a method in which the initial guess is not a finite set of points, but an entire smooth, differentiable closed loop.

A general flow (**??**) has no extremal principle associated with it, the simplification of so there is a great deal of arbitrariness in constructing a flow in a loop space. We shall introduce here several simplest conceivable cost functions which penalize mis-orientation of the local loop tangent vector $\tilde{v}(\tilde{x})$ relative to the dynamical velocity field $v(\tilde{x})$ of (**??**), and construct a flow in the loop space which minimizes this function. This flow is corralled by general topological features of the dynamics, with rather distant initial guesses converging to the desired orbit. Once the loop is sufficiently close to the periodic orbit, faster numerical algorithms can be employed to pin it down.

In order to set the notation, we shall distinguish between (see figure 37.5):

closed path: any closed (not necessarily differentiable) continuous curve $J \subset \mathcal{M}$.

loop: a smooth, differentiable closed curve $\tilde{x}(s) \in L \subset \mathcal{M}$, parametrized by $s \in [0, 2\pi]$ with $\tilde{x}(s) = \tilde{x}(s+2\pi)$, with the magnitude of the loop tangent

vector fixed by the (so far arbitrary) parametrization of the loop,

$$\tilde{v}(\tilde{x}) = \frac{d\tilde{x}}{ds}\,, \quad \tilde{x} = \tilde{x}(s) \in L\,.$$

annulus: a smooth, differentiable surface $\tilde{x}(s,\tau) \in L(\tau)$ swept by a family of loops $L(\tau)$, by integration along a fictitious time flow (see figure 37.6 (a))

$$\dot{\tilde{x}} = \frac{\partial \tilde{x}}{\partial \tau}\,.$$

periodic orbit: given a smooth vector field $v = v(x)$, $(x,v) \in \mathbf{T}\mathcal{M}$, periodic orbit $x(t) \in p$ is a solution of

$$\frac{dx}{dt} = v(x)\,, \quad \text{such that } x(t) = x(t+T_p),$$

where T_p is the shortest period of p.

37.4.1 Loop parametrizations

Euclidean length

$$d^2 s = \sum_i dx_i^2$$

then

$$\tilde{v}(\tilde{x}) = \frac{d\tilde{x}}{ds} = \hat{n}\,.$$

is the unit tnagent vector: geometrically intrinsic, dimensionless and geometrically natural - but dynamically unnutural, knows nothing about the flow v.

Some immediate choices of the metric

$$d^2 s = g^{ij} dx_i dx_j$$

Euclidean

$$g^{ij} = \delta^{ij}$$

Parallel velocity (1-dimensional)

$$g^{ij} = \frac{v^i v^j}{v^2}$$

time!ordered integration

Transverse velocity ($(d$-1)-dimensional)

$$g^{ij} = \delta^{ij} - \frac{v^i v^j}{v^2}$$

Local shear (too local to be appealing)

$$g^{ij} = \left(A^T A\right)^{ij}$$

where

$$A_{ij}(x) = \frac{\partial v_i(x)}{\partial x_j}$$

from (37.21).

The deformation after a finite time t is described by the fundamental matrix

$$M^t(x_0) = \mathbf{T} e^{\oint_L \frac{dx_\parallel}{v_\parallel} \mathbf{A}(x(\tau))} ,$$

where $\mathbf{T}$ stands for the *time-ordered* integration. Its eigenvalues and eigendirections describe the deformation of an initial infinitesimal sphere of neighboring trajectories into an ellipsoid a finite time t later.

Symmetric and diagonalizable matrix $\mathbf{M} = (M^t)^T M^t$, with real positive eigenvalues $\{|\Lambda_1|^2 \geq \ldots \geq |\Lambda_d|^2\}$, and a complete orthonormal set of eigenvectors of $\{\mathbf{e}^1, \ldots, \mathbf{e}^d\}$. In the $\mathbf{M}\mathbf{e}^i = |\Lambda_i|\mathbf{e}^i$ eigenbasis, we have (37.32)

$$\mathbf{e}^{iT} \cdot \mathbf{M} \cdot \mathbf{e}^j = \delta^{ij} |\Lambda_i|^2 , \tag{37.16}$$

Prefereable, as intrinsic to the loop (prove: Λ_i smooth conjugacy invariants), and the eigendirections describe the invariant unstable/stable manifolds. The cost functional now measures the growth of an error along the loop

$$F^2[\tilde{x}] = \oint_L ds\, (\tilde{v} - v)_i |\Lambda_i|^2 , \tag{37.17}$$

penalizing errors in unstable directions, and ignoring the errors in the strongly contarcting directions (as the flow anyway takes care of them).

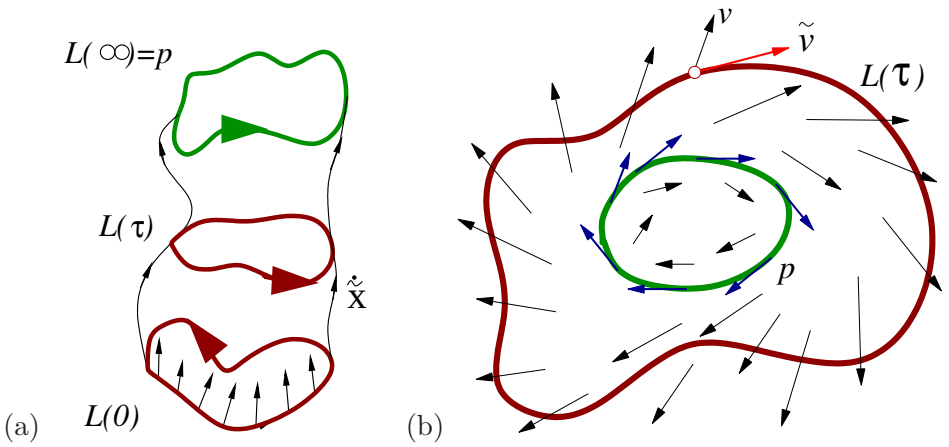

Figure 37.6: (a) An annulus $L(\tau)$ with vector field $\dot{\tilde{x}}$ connecting smoothly the initial loop $L(0)$ to a periodic orbit p. (b) In general the orientation of the loop tangent $\tilde{v}(\tilde{x})$ does not coincide with the orientation of the velocity field $v(\tilde{x})$; for a periodic orbit p it does so at every $x \in p$.

37.4.2 Newton Descent in the Loop Space

In the spirit of (**??**), we now define a cost functional for a loop and the associated fictitious time τ flow which sends an initial loop $L(0)$ via a loop family $L(\tau)$ into the periodic orbit $p = L(\infty)$, see figure 37.6 (a). The only thing that we are given is the velocity field $v(x)$, and we want to "comb" the loop $L(\tau)$ in such a way that its tangent field $\tilde{v}$ aligns with v everywhere, see figure 37.6 (b). The simplest cost functional for the job is

$$F^2[\tilde{x}] = \frac{1}{2\pi} \oint_L ds\, (\tilde{v} - v)^2\,, \quad \tilde{v} = \tilde{v}(\tilde{x}(s,\tau))\,, \quad v = v(\tilde{x}(s,\tau))\,. \tag{37.18}$$

Need to match the magnitude of the tangent field $\tilde{v}$ (measured in the loop parametrization units s) to the velocity field v (measured in the dynamical time units t). $|v|$ cannot vanish anywhere along the loop $L(\tau)$, as in that case the loop would be passing through an equilibrium point, and have infinite period.

Take a derivative of the cost functional $F^2[\tilde{x}]$ with respect to the (yet undetermined) fictitious time τ,

$$\frac{dF^2}{d\tau} = \frac{1}{\pi} \oint_L ds\, (\tilde{v} - v)\, \frac{d}{d\tau}(\tilde{v} - v)\,.$$

The simplest, exponentially decreasing cost functional is obtained by taking the $\tilde{x}(s,\tau)$ dependence on τ to be point-wise proportional to the deviation of the two vector fields

$$\frac{d}{d\tau}(\tilde{v} - v) = -(\tilde{v} - v)\,, \tag{37.19}$$

so the fictitious time flow drives the loop to $L(\infty) = p$, see figure 37.6 (a):

$$\tilde{v} - v = e^{-\tau}(\tilde{v} - v)|_{\tau=0}\,. \tag{37.20}$$

Making the $\tilde{x}$ dependence in (37.19) explicit we obtain our main result, the Newton descent PDE which evolves the initial loop $L(0)$ into the desired periodic orbit p

$$\frac{\partial^2 \tilde{x}}{\partial s \partial \tau} - A\frac{\partial \tilde{x}}{\partial \tau} - \frac{\partial}{\partial \tau} v = v - \tilde{v}\,, \qquad A_{ij}(x) = \frac{\partial v_i(x)}{\partial x_j} \tag{37.21}$$

in the fictitious time $\tau \to \infty$. Here A is the stability matrix of the flow (its integral around p yields the linearized stability matrix for the periodic orbit p).

37.4.3 A metric for the fictitous time flow?

Ideas:
invariant manifold wiath a few unstable directions
∞ strongly contarcting directions.
"noise" should be uniform in the rescaled coordinates.

As any pair of nearby points on a cycle returns to itself exactly at each cycle period, the eigenvalue of the fundamental matrix corresponding to the eigenvector along the flow necessarily equals unity for all periodic orbits. Hence flows require a separate treatment for the longitudinal direction. To find an isolated prime cycle p of period T_p, restrict the search to an infinitesimally thin tube $\mathcal{M}_p$ enveloping the cycle (see figure 1.11), and choose a local coordinate system with a longitudinal coordinate $dx_\parallel$ along the direction of the flow, and d transverse coordinates $x_\perp$

$$\int_{\mathcal{M}_p} dx_\perp dx_\parallel\, \delta\big(x_\perp - f^t_\perp(x)\big)\, \delta\Big(x_\parallel - f^t_\parallel(x)\Big)\ . \tag{37.22}$$

Let $v(x)$ be the magnitude of the velocity at the point x along the flow. $v(x)$ is strictly positive, as otherwise the orbit would stagnate for infinite time at $v(x) = 0$ points, and that would get us nowhere. Therefore we can
change $\sigma \to \tau'$ here
parametrize the longitudinal coordinate $x_\parallel$ by the flight time

$$x_\parallel(\tau) \;=\; \int_0^\tau d\sigma\, v(\sigma)$$

where $v(\sigma) = v(x_\parallel(\sigma))$, and L_p is the length of the circuit on which the periodic orbit lies, $\tau \in [0, T_p]$).

$$\Big(f^t_\parallel(x) - x_\parallel\Big) = \int_\tau^{t+\tau} d\sigma\, v(\sigma)\Big|_{mod\, L_p}$$

so that the integral around the longitudinal coordinate is rewritten as

time!ordered integration

$$\int_0^{L_p} dx_\parallel \, \delta\Big(x_\parallel - f_\parallel^t(x)\Big) \tag{37.23}$$

For the remaining transverse integration variables the fundamental matrix is defined in a reduced Poincaré surface of section $\mathcal{P}$ of constant $x_\parallel$. Linearization of the periodic flow transverse to the orbit yields

$$\int_{\mathcal{P}} dx_\perp \delta\Big(x_\perp - f_\perp^{rT_p}(x)\Big) = \frac{1}{\left|\det\left(\mathbf{1} - M_p^r\right)\right|} \,, \tag{37.24}$$

where M_p is the p-cycle $[d\times d]$ *transverse* fundamental matrix, and as in (14.5) we have to assume hyperbolicity, i.e., that the magnitudes of all transverse eigenvalues are bounded away from unity.

37.4.4 Cycle stabilities are cycle invariants

A neighborhood of a trajectory deforms as it is transported by a flow. In the linear approximation, the stability matrix $\mathbf{A}$ describes the shearing/compression/expansion of an infinitesimal neighborhood in an infinitesimal time step. The deformation after a finite time t is described by the fundamental matrix

$$M^t(x_0) = \mathbf{T} e^{\int_0^t d\tau \mathbf{A}(x(\tau))} \,,$$

where $\mathbf{T}$ stands for the *time-ordered* integration. Its eigenvalues and eigendirections describe the deformation of an initial infinitesimal sphere of neighboring trajectories into an ellipsoid a finite time t later. Nearby trajectories separate exponentially along unstable directions, approach each other along stable directions, and change slowly (algebraically) their distance along marginal directions. The fundamental matrix M^t is in general neither symmetric, nor diagonalizable by a rotation, nor do its (left or right) eigenvectors define an orthonormal coordinate frame. Furthermore, although the stability matrices are multiplicative along the flow, in dimensions higher than one their eigenvalues in general are not. This lack of multiplicativity has important repercussions for both classical and quantum dynamics.

☞ appendix I.1

⇓PRIVATE

☞ chapter 40

⇑PRIVATE

The 1-dimensional map cycle stability Λ_p is a product of derivatives over all points around the cycle, and is therefore independent of which periodic point is chosen as the initial one. In higher dimensions the form of the fundamental matrix $M_p(x_0)$ in (8.1) does depend on the choice of coordinates and the initial point $x_0 \in p$. Nevertheless, as we shall now show, the cycle stability *eigenvalues* are intrinsic property of a cycle also for multi-dimensional flows. Consider the ith eigenvalue, eigenvector pair $(\Lambda_{p,i}, \mathbf{e}_i)$ computed from M_p evaluated at a cycle point,

$$M_p(x)\mathbf{e}_i(x) = \Lambda_{p,i}\mathbf{e}_i(x) \,, \quad x \in p \,. \tag{37.25}$$

invariance!of flows
nonhyperbolic!flow

Consider another point on the cycle at time t later, $x' = f^t(x)$ whose fundamental matrix is $M_p(x')$. By the group property (4.33), $M^{T_p+t} = M^{t+T_p}$, and the fundamental matrix at x' can be written either as

$$M^{T_p+t}(x) = M^{T_p}(x')M^t(x) = M_p(x')M^t(x)\,, \quad \text{or} \quad M^{t+T_p}(x) = M^t(x)M_p(x)\,.$$

Multiplying (8.9) by $M^t(x)$, we find that the fundamental matrix evaluated at x' has the same eigenvalue,

$$M_p(x')\mathbf{e}_i(x') = \Lambda_{p,i}\mathbf{e}_i(x')\,, \quad \mathbf{e}_i(x') = M^t(x)\mathbf{e}_i(x)\,, \tag{37.26}$$

but with the eigenvector $\mathbf{e}_i$ transported along the flow $x \to x'$ to $\mathbf{e}_i(x') = M^t(x)\mathbf{e}_i(x)$. Hence, M_p evaluated anywhere along the cycle has the same set of stability eigenvalues $\{\Lambda_{p,1}, \Lambda_{p,2}, \cdots \Lambda_{p,d}\}$. As quantities such as $\operatorname{tr} M_p(x)$, $\det M_p(x)$ depend only on the eigenvalues of $M_p(x)$ and not on the starting point x, in expressions such as $\det\left(\mathbf{1} - M_p^r(x)\right)$ we may omit reference to any particular cycle point x:

YL: elaborate!

$$\det\left(\mathbf{1} - M_p^r\right) = \det\left(\mathbf{1} - M_p^r(x)\right) \quad \text{for any } x \in p\,. \tag{37.27}$$

We postpone the proof that the cycle stability eigenvalues are smooth conjugacy invariants of the flow to sect. 8.5.

37.4.5 Marginal eigenvalues

The presence of marginal eigenvalues signals either an invariance of the flow (which one should immediately exploit to simplify the problem), or a non-hyperbolicity of a flow (a source of much pain, hard to avoid).

chapter 21

A periodic orbit of a continuous flow always has at least one marginal eigenvalue. As $M^t(x)$ transports the velocity field $v(x)$ by (4.7), after a complete period

$$M_p(x)v(x) = v(x)\,, \tag{37.28}$$

so a periodic orbit of a *flow* always has an eigenvector $\mathbf{e}_{\|}(x) = v(x)$ parallel to the local velocity field with the unit eigenvalue

$$\Lambda_{p,\|} = 1\,. \tag{37.29}$$

7.2
page 118

The continuous invariance that gives rise to this marginal eigenvalues is the invariance of a cycle under a translation of its points along the cycle. As we shall see in sect. 14.3, this marginal stability direction can be eliminated by cutting the cycle by a Poincaré section and eliminating the continuous flow fundamental matrix in favor of the fundamental matrix of the Poincaré return map.

say "momodromy"?

37.4.6 Lyapunov exponents

Lyapunov exponent
time!average

The mean growth rate of the distance $|\delta x(t)|/|\delta x(0)|$ between neighboring trajectories (10.27) is given by the *Lyapunov exponent*

$$\lambda = \lim_{t\to\infty} \frac{1}{t} \ln |\delta x(t)|/|\delta x(0)| \tag{37.30}$$

(For notational brevity we shall often suppress the dependence of quantities such as $\lambda = \lambda(x_0)$, $\delta x(t) = \delta x(x_0, t)$ on the initial point x_0 and the time t). For infinitesimal δx we know the $\delta x_i(t)/\delta x_j(0)$ ratio exactly, as this is by definition the fundamental matrix (4.32)

$$\lim_{\delta x\to 0} \frac{\delta x_i(t)}{\delta x_j(0)} = \frac{\partial x_i(t)}{\partial x_j(0)} = M^t_{ij}(x_0)\,,$$

so the leading Lyapunov exponent can be computed from the linear approximation (4.25)

$$\lambda = \lim_{t\to\infty} \frac{1}{t} \ln \frac{\left|M^t(x_0)\delta x(0)\right|}{|\delta x(0)|} = \lim_{t\to\infty} \frac{1}{2t} \ln \left|\hat{n}^T (M^t)^T M^t \hat{n}\right| . \tag{37.31}$$

In this formula the scale of the initial separation drops out, only its orientation given by the unit vector $\hat{n} = \delta x/|\delta x|$ matters. The eigenvalues of M are either real or come in complex conjugate pairs. As M is in general not symmetric and not diagonalizable, it is more convenient to work with the symmetric and diagonalizable matrix $\mathbf{M} = (M^t)^T M^t$, with real positive eigenvalues $\{|\Lambda_1|^2 \geq \ldots \geq |\Lambda_d|^2\}$, and a complete orthonormal set of eigenvectors of $\{u_1, \ldots, u_d\}$. Expanding the initial orientation $\hat{n} = \sum(\hat{n}\cdot u_i)u_i$ in the $\mathbf{M}u_i = |\Lambda_i|u_i$ eigenbasis, we have

⇓PRELIMINARY
☞ remark 4.2
⇑PRELIMINARY

$$\hat{n}^T \mathbf{M} \hat{n} = \sum_{i=1}^{d} (\hat{n}\cdot u_i)^2 |\Lambda_i|^2 = (\hat{n}\cdot u_1)^2 e^{2\lambda_1 t} \left(1 + O(e^{-2(\lambda_1-\lambda_2)t})\right) , \tag{37.32}$$

where $t\lambda_i = \ln|\Lambda_i(x_0, t)|$, and we assume that $\lambda_1 > \lambda_2 \geq \lambda_3 \cdots$. For long times the largest Lyapunov exponent dominates exponentially (10.29), provided the orientation $\hat{n}$ of the initial separation was not chosen perpendicular to the dominant expanding eigendirection u_1. The Lyapunov exponent is the time average

$$\begin{aligned} \overline{\lambda(x_0)} &= \lim_{t\to\infty} \frac{1}{t} \left\{ \ln|\hat{n}\cdot u_1| + \ln|\Lambda_1(x_0, t)| + O(e^{-2(\lambda_1-\lambda_2)t}) \right\} \\ &= \lim_{t\to\infty} \frac{1}{t} \ln|\Lambda_1(x_0, t)|\,, \end{aligned} \tag{37.33}$$

where $\Lambda_1(x_0,t)$ is the leading eigenvalue of $M^t(x_0)$. By choosing the initial displacement such that $\hat{n}$ is normal to the first (i-1) eigendirections we can define not only the leading, but all Lyapunov exponents as well:

$$\overline{\lambda_i(x_0)} = \lim_{t\to\infty} \frac{1}{t} \ln |\Lambda_i(x_0,t)| \,, \qquad i = 1, 2, \cdots, d \,. \tag{37.34}$$

edit figure 10.5

The leading Lyapunov exponent now follows from the fundamental matrix by numerical integration of (4.34). The equations can be integrated accurately for a finite time.

make problem set, mention rescaling to avoid overflows

37.4.7 Evolution operator for Lyapunov exponents

The key idea is to extending the dynamical system by the tangent space of the flow, suggested by the standard numerical methods for evaluation of Lyapunov exponents: start at x_0 with an initial infinitesimal tangent space vector $\eta(0) \in \mathbf{T}\mathcal{M}_x$, and let the flow transport it along the trajectory $x(t) = f^t(x_0)$.

The dynamics in the $(x,\eta) \in U \times TU_x$ space is governed by the system of equations of variations [7.1]:

$$\dot{x} = \mathbf{v}(x) \,, \quad \dot{\eta} = \mathbf{D}\mathbf{v}(x)\eta \,.$$

Here $\mathbf{D}\mathbf{v}(x)$ is the derivative matrix of the flow. We write the solution as

$$x(t) = f^t(x_0) \,, \quad \eta(t) = M^t(x_0)\cdot\eta_0 \,, \tag{37.35}$$

with the tangent space vector η transported by the stability matrix $M^t(x_0) = \partial x(t)/\partial x_0$.

As explained in sect. 4.1, the growth rate of this vector is multiplicative along the trajectory and can be represented as $\eta(t) = |\eta(t)|/|\eta(0)|\mathbf{u}(t)$ where $\mathbf{u}(t)$ is a "unit" vector in some norm $||.||$. For asymptotic times and for almost every initial $(x_0,\eta(0))$, this factor converges to the leading eigenvalue of the linearized stability matrix of the flow.

We implement this multiplicative evaluation of stability eigenvalues by adjoining the d-dimensional transverse tangent space $\eta \in \mathbf{T}\mathcal{M}_x$; $\eta(x)\mathbf{v}(x) = 0$ to the (d+1)-dimensional dynamical evolution space $x \in \mathcal{M} \subset \mathbb{R}^{d+1}$. In order to determine the length of the vector η we introduce a homogeneous differentiable scalar function $g(\eta) = ||\eta||$. It has the property $g(\Lambda\eta) = |\Lambda|g(\eta)$ for any Λ. An example is the projection of a vector to its dth component

$$g\begin{pmatrix} \eta_1 \\ \eta_2 \\ \cdots \\ \eta_d \end{pmatrix} = |\eta_d| \,.$$

Any vector $\eta \in TU_x$ can now be represented by the product $\eta = \Lambda \mathbf{u}$, where $\mathbf{u}$ is a "unit" vector in the sense that its norm is $||\mathbf{u}|| = 1$, and the factor

$$\Lambda^t(x_0, \mathbf{u}_0) = g(\eta(t)) = g(M^t(x_0) \cdot \mathbf{u}_0) \tag{37.36}$$

is the multiplicative "stretching" factor.

Unlike the leading eigenvalue of the Jacobian the stretching factor is multiplicative along the trajectory:

$$\Lambda^{t'+t}(x_0, \mathbf{u}_0) = \Lambda^{t'}(x(t), \mathbf{u}(t))\, \Lambda^t(x_0, \mathbf{u}_0).$$

I.1 page 956

The $\mathbf{u}$ evolution constrained to $E\mathbf{T}_{g,x}$, the space of unit transverse tangent vectors, is given by rescaling of (37.35):

$$\mathbf{u}' = R^t(x, \mathbf{u}) = \frac{1}{\Lambda^t(x, \mathbf{u})} M^t(x) \cdot \mathbf{u}\,. \tag{37.37}$$

Eqs. (37.35), (37.36) and (37.37) enable us to define a *multiplicative* evolution operator on the extended space $U \times E\mathbf{T}_{g,x}$

$$\mathcal{L}^t(x', \mathbf{u}'; x, \mathbf{u}) = \delta\big(x' - f^t(x)\big)\, \frac{\delta\big(\mathbf{u}' - R^t(x, \mathbf{u})\big)}{|\Lambda^t(x, \mathbf{u})|^{\beta-1}}\,, \tag{37.38}$$

where β is a variable.

We note next that if the trajectory $f^t(x)$ is periodic with period T, the tangent space contains d periodic solutions

$$\mathbf{e}_i(x(T+t)) = \mathbf{e}_i(x(t))\,, \quad i = 1, ..., d,$$

corresponding to the d unit eigenvectors $\{\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_d\}$ of the transverse stability matrix, with "stretching" factors (37.36) given by its eigenvalues

$$M_p(x) \cdot \mathbf{e}_i(x) = \Lambda_{p,i}\, \mathbf{e}_i(x)\,, \quad i = 1, ..., d. \qquad \text{(no summation on } i)$$

The $\int d\mathbf{u}$ integral in (**??**) picks up contributions from these periodic solutions. In order to compute the stability of the ith eigendirection solution, it is convenient to expand the variation around the eigenvector $\mathbf{e}_i$ in the stability matrix eigenbasis $\delta\mathbf{u} = \sum \delta u_\ell\, \mathbf{e}_\ell$. The variation of the map (37.37) at a complete period $t = T$ is then given by

$$\begin{aligned} \delta R^T(\mathbf{e}_i) &= \frac{M \cdot \delta\mathbf{u}}{g(M \cdot \mathbf{e}_i)} - \frac{M \cdot \mathbf{e}_i}{g(M \cdot \mathbf{e}_i)^2} \left(\frac{\partial g(\mathbf{e}_i)}{\partial \mathbf{u}} \cdot M \cdot \delta\mathbf{u} \right) \\ &= \sum_{k \neq i} \frac{\Lambda_{p,k}}{\Lambda_{p,i}} \left(\mathbf{e}_k - \mathbf{e}_i \frac{\partial g(\mathbf{e}_i)}{\partial u_k} \right) \delta u_k\,. \end{aligned} \tag{37.39}$$

periodic!orbit extraction—)

The δu_i component does not contribute to this sum since $g(\mathbf{e}_i + du_i\mathbf{e}_i) = 1 + du_i$ implies $\partial g(\mathbf{e}_i)/\partial u_i = 1$. Indeed, infinitesimal variations $\delta\mathbf{u}$ must satisfy

$$g(\mathbf{u}+\delta\mathbf{u}) = g(\mathbf{u}) = 1 \quad \Longrightarrow \quad \sum_{\ell=1}^{d} \delta u_\ell \frac{\partial g(\mathbf{u})}{\partial u_\ell} = 0\,,$$

so the allowed variations are of form

$$\delta\mathbf{u} = \sum_{k\neq i} \left(\mathbf{e}_k - \mathbf{e}_i \frac{\partial g(\mathbf{e}_i)}{\partial u_k}\right) c_k\,, \quad |c_k| \ll 1\,,$$

and in the neighborhood of the $\mathbf{e}_i$ eigenvector the $\int d\mathbf{u}$ integral can be expressed as

$$\int_g d\mathbf{u} = \int \prod_{k\neq i} dc_k\,.$$

Commentary

Prepare Lozi map exercise

Remark 37.1 Piece-wise linear maps. The Lozi map (3.17) is linear, and 100,000's of cycles can be easily computed by [2x2] matrix multiplication and inversion.

Remark 37.2 Relaxation method. The relaxation (or gradient) algorithm is one of the methods for solving extremal problems [37.13]. The method described above was introduced by Biham and Wenzel [37.1], who have also generalized it (in the case of the Hénon map) to determination of *all* 2^n cycles of period n, real or complex [37.2]. The applicability and reliability of the method is discussed in detail by Grassberger, Kantz and Moening [37.5], who give examples of the ways in which the method fails: (a) it might reach a limit cycle rather than a equilibrium saddlepoint (that can be remedied by the complex Biham-Wenzel algorithm [37.2]) (b) different symbol sequences can converge to the same cycle (i.e., more refined initial conditions might be needed). Furthermore, Hansen (ref. [37.7] and chapter 4. of ref. [1.7]) has pointed out that the method cannot find certain cycles for specific values of the Hénon map parameters.

In practice, the relaxation method for determining periodic orbits of maps appears to be effective almost always, but not always. It is much slower than the multipoint shooting method of sect. 17.4.1, but also much quicker to program, as it does not require evaluation of stability matrices and their inversion. If the complete set of cycles is required, the method has to be supplemented by other methods.

Remark 37.3 Hybrid Newton-Raphson/relaxation methods. The method discussed in sect. 37.2 was introduced by Schmelcher *et al* [37.9]. The method was extended

to flows by means of the Poincaré surface of section technique in ref. [37.10]. It is also possible to combine the Newton-Raphson method and (37.13) in the construction of a transformed map [37.14]. In this approach, each step of the iteration scheme is a linear superposition of a step of the stability transformed system and a step of the Newton-Raphson algorithm. Far from the linear neighborhood the weight is dominantly on the globally acting stability transformation algorithm. Close to the fixed point, the steps of the iteration are dominated by the Newton-Raphson procedure.

Remark 37.4 Relation to the Smale horseshoe symbolic dynamics. For a complete horseshoe Hénon repeller (a sufficiently large), such as the one given in figure 37.2, the signs $\sigma_i \in \{1, -1\}$ are in a 1-to-1 correspondence with the Smale horsheshoe symbolic dynamics $s_i \in \{0, 1\}$:

$$s_i = \begin{cases} 0 & \text{if } \sigma_i = -1\,, \quad x_i < 0 \\ 1 & \text{if } \sigma_i = +1\,, \quad x_i > 0 \end{cases} \,. \tag{37.40}$$

For arbitrary parameter values with a finite subshift symbolic dynamics or with arbitrarily complicated pruning, the relation of sign sequences $\{\sigma_1, \sigma_2, \cdots, \sigma_n\}$ to the itineraries $\{s_1, s_2, \cdots, s_n\}$ can be much subtler; this is discussed in ref. [37.5].

Remark 37.5 A compilation of the Hénon map numerical results. For the record - the most accurate estimates of various averages for the Hénon map, Hénon's parameters choice $a = 1.4$, $b = 0.3$, known to the authors, are: the topological entropy (13.1) is $h = 0.4645??$, the Lyapunov exponent $= 0.463$, the Hausdorff dimension $D_H = 1.274(2)$.

Remark 37.6 Software for searching for periodic solutions. Bard Ermentrout's description of AUTO makes it look very much like our variational method [37.15, 37.16]: AUTO solves boundary value problems by solving

$$\frac{x_{n+1} - x_n}{\Delta t} - F(x_n) = 0 \tag{37.41}$$

as a big system of algebraic equations, $G(x) = 0$. One needs to fix marginal directions; that is called the *colocation* method.

Remark 37.7 Ikeda map. Ikeda map (37.11) was introduced in ref. [37.12] is a model which exhibits complex dynamics observed in nonlinear optical ring cavities.

Remark 37.8 Relaxation for continuous time flows. For a d-dimensional flow $\dot{x} = v(x)$, the method described above can be extended by considering a Poincaré surface of section. The Poincaré section yields a map f with dimension d-1, and the above discrete iterative maps procedures can be carried out. A method that keeps the trial orbit continuous throughout the calculation is the Newton descent, a variational method for finding periodic orbits of continuous time flows, is described in refs. [37.15, 37.16].

Remark 37.9 Stability ordering. The parameter $\Delta\tau$ in (37.13) is a key quantity here. It is related to the stability of the desired cycle in the transformed system: The more unstable a fixed point is, the smaller $\Delta\tau$ has to be to stabilize it. With increasing cycle periods, the unstable eigenvalue of the stability matrix increases and therefore $\Delta\tau$ has to be reduced to achieve stabilization of all fixed points. In many cases the least unstable cycles of a given period n are of physically most important [37.11]. In this context $\Delta\tau$ operates as a stability filter. It allows the selective stabilization of only those cycles which posses Lyapunov exponents smaller than a cut-off value. If one starts the search for cycles within a given period n with a value $\Delta\tau \approx O(10^{-1})$, and gradually lowers $\Delta\tau$ one obtains the sequence of all unstable orbits of order n sorted with increasing values of their Lyapunov exponents. For the specific choice of $\mathbf{C}$ the relation between $\Delta\tau$ and the stability coefficients of the fixed points of the original system is strictly monotonous. Transformed dynamical systems with other $\mathbf{C}$'s do not obey such a strict behavior but show a rough ordering of the sequence of stability eigenvalues of the fixed points stabilized in the course of decreasing values for $\Delta\tau$. As explained in sect. 18.6, stability ordered cycles are needed to order cycle expansions of dynamical quantities of chaotic systems for which a symbolic dynamics is not known. For such systems, an ordering of cycles with respect to their stability has been proposed [18.13, 18.14, 18.12], and shown to yield good results in practical applications.

Remark 37.10 Action extremization method. The action extremization (sect. 37.3) as a numerical method for finding cycles has been introduced independently by many people. We have learned it from G. Russberg, and from M. Sieber's and F. Steiner's hyperbola billiard computations [37.17, 37.18]. The convergence rate is really impressive, for the Sinai billiard some 5000 cycles are computed within CPU seconds with rather bad initial guesses.

Variational methods are the key ingredient of the Aubry-Mather theory of area-preserving twist maps (known in the condensed matter literature as the Frenkel-Kontorova models of 1-dimensional crystals), discrete-time Hamiltonian dynamical systems particularly suited to explorations of the K.A.M. theorem. Proofs of the Aubry-Mather theorem [37.20] on existence of quasi-periodic solutions are variational. It was quickly realized that the variational methods can also yield reliable, high precision computations of long periodic orbits of twist map models in 2 or more dimensions, needed for K.A.M. renormalization studies [37.19].

A fictitious time gradient flow similar to the one discussed here in sect. 37.1 was introduced by Anegent [37.21] for twist maps, and used by Gole [37.22] in his proof of the Aubry-Mather theorem. Mathematical bounds on the regions of stability of K.A.M. tori are notoriously restrictive compared to the numerical indications, and de la Llave, Falcolini and Tompaidis [37.23, 37.24] have found the gradient flow formulation advantageous both in studies of the analyticity domains of the K.A.M. stability, as well as proving the Aubry-Mather theorem for extended systems (for a pedagogical introduction, see the lattice dynamics section of ref. [37.25]).

All of the twist-maps work is based on extremizing the discrete dynamics version of the action S (in this context sometimes called a "generating function"). However, in their investigations in the complex plane, Falcolini and de la Llave [37.23] do find it useful to minimize instead $S\bar{S}$, analogous to our cost function (37.3).

Résumé

fill in

Unlike the Newton-Raphson method, variational methods are very robust. As each step around a cycle is short, they do not suffer from exponential instabilities, and with rather coarse initial guesses one can determine cycles of arbitrary length.

"exercise" - formulate such method for flows
